DIAGNOSIS OF TIGHT MITRAL STENOSIS

Abe Ravin, M.D., N. Balfour Slonim, M.D., Oscar J. Balchum, M.D., Sidney H. Dressler, M.D.
and
John B. Grow, M.D., Denver

Recent advances in the surgical treatment of mitral stenosis have made the diagnosis of tight mitral stenosis important. Evidence is accumulating that mitral commissurotomy performed in patients with tight mitral stenosis is of benefit and can be performed with a comparatively low mortality in selected cases. Patients with mild mitral stenosis and with severe mitral insufficiency or aortic valvular lesions may present somewhat similar pictures, but would not be candidates for surgical treatment until such time as operative approaches to the correction of mitral insufficiency or aortic insufficiency and stenosis have proved their worth. Although there is a tendency, at present, to limit the operation to those patients who show tight mitral stenosis without significant associated lesions, it seems possible that correction of the mitral stenosis may be of value whenever it is severe, regardless of associated lesions. The purpose of this presentation is to describe the factors that are important in the diagnosis of tight mitral stenosis. Seventeen patients with this diagnosis were carefully studied clinically and by means of cardiac catheterization. These patients were subsequently operated on, and the presence of a tight mitral stenosis demonstrated. None of the mitral valves would admit the tip of the surgeon's index finger. Since the area of the finger tip was approximately 1 sq. cm., the valve areas were all less, often much less, than 1 sq. cm.

Other valvular lesions of minor degree were present in these patients but influenced the general picture little, if at all. Mitral insufficiency was frequently present but, in view of the small valve opening, was necessarily slight. Faint diastolic murmurs along the left border of the sternum were considered as indicating some aortic insufficiency, but no other evidences of this lesion were present. Some of these murmurs may have been due to pulmonary insufficiency. Tricuspid lesions were recognized in at least two cases and, in minor degree, may have been present in others. The important findings in these patients are shown in table 1 and are discussed below.

AUSCULTATION

The auscultatory findings (table 1, columns 4 through 8) are of major importance, and the diagnosis of tight mitral stenosis can be made in many cases on the basis of auscultation alone.

Murmurs.—For the diagnosis of mitral stenosis the characteristic mid-diastolic murmur, whether loud or faint, should be present. The murmur of mitral stenosis has the following characteristics:

1. It is best heard at the apex and when faint may be confined to a very small area. As the murmur becomes more intense, it is heard over a wider area; however, even when very intense, it may be confined to a relatively small area.
2. The murmur is best heard when the patient is recumbent and in the left lateral position. Even when it is very loud in this position, it may be heard poorly or not at all in the sitting position. Listening to a patient only in the sitting or standing position does not constitute a complete examination. When faint, the murmur may be best heard for several beats just after the patient has assumed the left lateral position or just after the patient returns to the recumbent position.
3. The murmur in its early stages is rather low-pitched and rumbling in character and therefore best heard with the bell of the stethoscope. To hear faint murmurs, one must hold the bell lightly against the skin because the intensity of the murmur is decreased by pressure. As the intensity of the murmur increases, it becomes harsher and may be heard equally well with the bell or the diaphragm.

This study was aided by a grant from the Life Insurance Medical Research Fund.

From the Cardiopulmonary Laboratory of the National Jewish Hospital at Denver and the Department of Medicine of the University of Colorado Medical Center.

Public Health Service Postdoctorate Research Fellow of the National Heart Institute (Dr. Slonim) and Fellow of the National Research Council (Dr. Balchum).

4. In the early stages the murmur of mitral stenosis is entirely mid-diastolic. As the stenosis progresses or the heart rate increases, the murmur, which begins in mid-diastole, now continues to the first heart sound, often with a presystolic accentuation. Rarely does a presystolic murmur occur without a mid-diastolic murmur. These cases must be regarded with suspicion, because various changes occurring about the time of the first heart sound may give the impression of a presystolic murmur. A faint mid-diastolic murmur associated with a loud presystolic murmur may indicate a valve that is moderately stenotic but not as tight as in those cases in which the murmur is loud from its onset in mid-diastole. In the presence of auricular fibrillation the duration of the murmur may be an index of the severity of the stenosis.

5. Tachycardia due to exertion or other causes makes the murmur more evident.

In tight mitral stenosis the mid-diastolic murmur is usually loud or moderately loud. Occasionally it may be faint, and rarely it may be absent. The position of the [illegible] onary emphysema may at

degrees of right heart failure. Thus a patient who has a moderately loud mid-diastolic murmur before failure occurs may have only a faint murmur with the onset of fibrillation and/or failure. In patients with known rheumatic heart disease who are in failure and do not have evidence of active rheumatic fever or a significant aortic valvular lesion to account for the failure, the diagnosis of tight mitral stenosis may tentatively be made on the basis of the other findings described below, even if the mid-diastolic murmur is faint.

When a loud mid-diastolic murmur is heard, the systolic murmur of mitral insufficiency is usually absent or faint, and only occasionally is it moderately loud. The murmur of slight or moderate mitral insufficiency is high-pitched and blowing and is best heard at the apex with the diaphragm of the stethoscope. If the diastolic murmur is loud and the systole is short, the systolic murmur may be difficult to hear. In general, it is true that the louder the systolic murmur the less intense the diastolic murmur, and vice versa. In the patients of our series the stenosis was so marked that there could not have been [illegible] fficiency, and in no instance was there a loud [illegible]

mild or moderate degree and the insufficiency is likely to be the more important lesion Since insufficiency is often aggravated by the operation, patients whose insufficiency is judged to be the more important lesion would not appear to be candidates for the operation at present.

The systolic murmur of tricuspid insufficiency often becomes evident as right heart failure develops and should not be confused with the murmur of mitral insufficiency. The murmur of tricuspid insufficiency is of maximum intensity just to the left of the lower end of the sternum and fades out laterally, so that it is usually faint at the point of maximum intensity of the mid-diastolic murmur, while the murmur of mitral insufficiency is loud at the apex and well heard laterally. When the tricuspid insufficiency is marked, cervical venous pulsation and liver pulsation may be of help in the diagnosis.

Many of the patients had a high-pitched, early diastolic murmur along the left border of the sternum, best heard with the diaphragm of the stethoscope. This murmur was usually considered to be indicative of aortic insufficiency, although in some instances it might have represented pulmonary insufficiency. This murmur, even when well heard at the apex, should not be confused with the murmur of mitral stenosis, because of the difference in timing, pitch, and points of maximum intensity.

Heart Sounds.—The intensity of the first heart sound is usually increased. It is occasionally diminished, but the presence of a markedly diminished first heart sound should be regarded with suspicion, for it is more likely to occur when mitral insufficiency is the important lesion. Accentuation of the second heart sound in the pulmonic area is of importance as an indication of increased pressure in the pulmonary artery. However, accentuation of the pulmonic second sound does not invariably occur when pulmonary arterial hypertension is present. It may be absent because of the position of the artery, the presence of pulmonary emphysema, or other causes. The opening click of the mitral valve was present in several of our patients, but its value as a diagnostic sign for tight mitral stenosis could not be evaluated.

FLUOROSCOPIC AND ROENTGENOGRAPHIC OBSERVATIONS

Next in importance to the auscultatory findings in the diagnosis of tight mitral stenosis is the roentgenologic evidence of the presence of left auricular enlargement and the absence of left ventricular enlargement. Left auricular enlargement was marked in almost every case and was well seen in both the posteroanterior view and in the left lateral esophogram. It was well seen during fluoroscopic examination when the points of opposite pulsation along the left cardiac contour could easily be determined. If orthodiascopic study is made, the exact length of the auricular segment may be determined and a measure of the degree of left auricular enlargement obtained. This segment normally does not exceed 2.2 cm. in length[1]; in our patients it was often 4.5 to 5 cm. in length. The enlargement of the left auricle is of importance as an indication of the degree of mitral stenosis only when taken in conjunction with the other criteria, especially those that rule out marked mitral insufficiency. Although the degree of auricular enlargement in mitral stenosis may often be pronounced, similar degrees of enlargement may occur in mitral insufficiency and the most pronounced enlargement is often seen in patients with fairly severe mitral insufficiency associated with moderate stenosis.

The left ventricle (as judged by cardiac contour) was considered to be not enlarged in nine cases and possibly slightly enlarged in eight cases. The absence of left ventricular enlargement is reflected in the absence of pronounced increases in transverse diameter in a group of patients all showing evidence of advanced heart disease. The cardiothoracic ratio was 50% or greater in only 10 patients. The transverse diameter of the heart was greater than the transverse diameter predicted on the basis of height and weight[2] in 16 patients, and the average increase was 25%. Although the absence of left ventricular enlargement is a factor against severe mitral insufficiency, its presence could at times be due to aortic valvular lesions or arterial hypertension.

The pulmonary artery and its major branches were considered to be enlarged in almost every instance. The prominence of the pulmonary artery served as a rough index of the pulmonary arterial pressure, since patients with the most prominent arteries had the highest pulmonary arterial pressures. As a result of the increased prominence of the left auricular appendage and pulmonary artery, all the patients showed straightening or even bulging of the left cardiac contour, the so-called mitral configuration.

Enlargement of the right ventricle was considered to be present in a majority of instances but was much more difficult to assess. The lung fields showed increased vascularity in all but two cases, with prominence of the vascular pattern, nodular densities, and, in several instances, multiple small calcifications.

ELECTROCARDIOGRAPHIC OBSERVATIONS

Since in the course of mitral stenosis an increased pressure develops in the left auricle and later in the right ventricle, these chambers of the heart often show hypertrophy and enlargement. In 16 patients we made a detailed study of the electrocardiogram in order to determine its value in the detection of these changes.

Left auricular hypertrophy and enlargement may be evidenced by P wave changes or by the presence of auricular fibrillation, for auricular fibrillation in rheumatic heart disease usually indicates the presence of a large left auricle under strain. Auricular fibrillation was present in 7 of the 16 electrocardiograms, and there was one instance of persistent auricular flutter. P wave changes occurred in all the remaining eight patients, with regular rhythm. These changes consisted of broad notched P waves, most clearly seen in leads 1 and 2. Increased amplitude of the P waves occurred at times but was not striking. This is in accord with the observation that tall P waves are more likely to occur with right auricular hypertrophy than with left.[3] The finding of either P wave changes or auricular fibrillation is in accord with the roentgenographic observation of enlargement of the left auricle in all 16 cases.

Electrocardiographic criteria for right ventricular hypertrophy have been defined by Sokolow and Lyon,[4] who used the unipolar and precordial limb leads, and by Schack, Rosenman, and Katz,[5] who employed only the unipolar limb leads. These criteria are listed in table 2, together with the data obtained from the electrocardiograms of our patients. A, B, C, and D are the criteria given by Sokolow. Under A are given the measurements for the voltages of the R and S waves in the precordial and unipolar limb leads and the various sums and ratios of these voltages. It can be seen that in only a few of our cases was the presence of abnormalities shown in these measurements, the greatest number being 5 patients out of the 16 who showed an R:S ratio in V_1 greater than 1 (criterion A-9). Four of these five patients also showed delayed ventricular activation time in V_1 or V_2 (criterion B). Changes in the RS-T segment and T waves occurred in only two (criterion C).

TABLE 2.—*Evidence of Right Ventricular Hypertrophy in Patients with Mitral Stenosis*

	Total	
	+	0
A. Voltage of R and S waves		
1. R wave in V_1 7 mm. or greater	3	13
2. S wave in V_1 less than 2 mm.	3	13
3. S wave in V_5 or V_6 7 mm. or greater	3	13
4. R in V_1 + S in V_6 greater than 10.5 mm.	3	13
5. R in V_6 less than 5 mm.	0	16
6. Ratio of R:S in V_6 = 1 or less	2	14
7. R in aV_r = 5 mm. or more	0	16
8. $\frac{\text{Ratio R:S in } V_5}{\text{Ratio R:S in } V_1}$ = .4 or less	4	12
9. Ratio R:S in V_1 greater than 1	5	11

E. Sum of ratios R:S in aV_l and aV_f Less than 13	3	13
Ratio R:S in aV_r greater than .7	3	13
Total voltages in aV_r, aV_l and aV_f greater than 42	1	15

No. of positive criteria shown by a given patient	0	1	3	7	10	12
No. of patients showing this no. of criteria	5	6	1	2	1	1

The changes in the unipolar limb leads in right ventricular hypertrophy given by Schack, Rosenman, and Katz[5] are shown in table 2 (criterion E). Only six patients showed abnormal values in any one of the criteria presented by Schack and his co-workers, no patient having more than one abnormal value.

The electrocardiographic position of the heart in these patients was vertical in 11, semi-vertical in 2, and intermediate in 3. There was accordingly right axis deviation (axis greater than +90 degrees) in six patients, and a tendency to right axis deviation (+80 to +90 degrees) in three patients. The remaining seven showed a normal axis. Although a vertical electrocardiographic position of the heart is of no significance when the heart size is normal, its occurrence in patients with cardiac disease and enlarged hearts is much more significant. In mitral stenosis, whether as a result of greater electrical potentials arising from the hypertrophied right ventricle or as a result of changes in the anatomic position of the heart, the electrocardiographic position of the heart tends to be vertical. In the case in which the enlargement of the heart is mostly left ventricular, the electrocardiographic position tends to be horizontal. The occurrence of a horizontal electrocardiographic position of the heart and corresponding left axis deviation suggests the presence and functional importance of mitral insufficiency or aortic valvular lesions rather than tight mitral stenosis.

Table 2 shows that in only two patients did the electrocardiogram exhibit abnormalities in over one-half of the criteria that are said to be of value in the detection of right ventricular hypertrophy. Only four (25%) of the patients had abnormalities in five or more of the criteria. One must assume either that very little right ventricular hypertrophy existed in these patients or that the electrocardiogram is of limited value in the detection of right ventricular hypertrophy until it is severe.

Postmortem findings in two patients showed right ventricular walls 4 to 6 mm. and 5 to 6 mm., respectively, in thickness, approximately twice that of the normal heart; yet the electrocardiograms met only 3 and 1, respectively, of the 20 criteria. All these patients had a long history of rheumatic heart disease with mitral stenosis, and the mean pulmonary arterial pressures were increased in all but three at rest and in all during mild exercise. It is reasonable, therefore, to conclude that right ventricular hypertrophy existed but that it apparently has to be severe in order to be detectable by electrocardiography.

CLINICAL DATA

Functional Status.—The occurrence of no limitation or slight limitation of physical activity would seem unlikely in the presence of a tight mitral stenosis of the type considered here. Although these patients get along remarkably well at rest, the inability to increase the cardiac output to any significant degree prevents their doing well on exertion. Some of them may for a while be able to increase their cardiac output by rather pronounced increases in pulmonary arterial pressure and thus apparently are in class 2.[6] They will, however, show a gradual deterioration in their ability to do physical activity and soon are clearly in class 3, that is, less than ordinary physical activity will cause discomfort.

Many patients with mitral stenosis get along well for years, for example, women who bear many children and patients who lead active lives and die at an advanced age of unrelated causes. These patients usually have mitral stenosis of only moderate degree. A valve area of 1.5 sq. cm. or more permits a cardiac output compatible with a rather active life.[7] Such valve areas are considerably less than the normal 4 to 6 sq. cm., yet greater than the mitral valve areas of our patients.

rt Association classification.

Attacks of Paroxysmal Auricular Fibrillation or Tachycardia.—Although these occur in many types of cardiac disease, patients with mitral stenosis and enlarged left auricles are particularly prone to have them and are often more ill with these attacks than are other cardiac patients. Persons with mitral stenosis tolerate tachycardia very poorly, because of their dependence on a diastolic filling period adequate for left ventricular filling. As the tachycardia shortens diastole, left ventricular filling decreases markedly and the cardiac output, low initially, falls to even lower levels. It is not uncommon for marked hypotension or anginal pain to develop during these attacks in such patients.

Episodes of Pulmonary Edema and Congestive Failure.—In a patient with the auscultatory findings of mitral stenosis and with only moderate cardiac enlargement, the occurrence of episodes of pulmonary edema or congestive failure suggests that the mitral stenosis is tight. These episodes are less significant when there is pronounced cardiac enlargement. Pulmonary edema is often precipitated by tachycardia.

Hemoptysis.—Hemoptysis is a classical sign of mitral stenosis, but its value as an index of the severity of mitral stenosis depends on the size of the heart. Hemoptysis in a patient with a heart that is only moderately enlarged suggests the presence of a tight mitral stenosis. Arterial embolization is not necessarily suggestive of tight mitral stenosis.

CARDIAC CATHETERIZATION

This procedure is widely used at present, and its importance in selection of patients for mitral commissurotomy has been emphasized. Valuable physiological data are certainly obtained by catheterization, for example, the cardiac output and index at rest and during exercise, the pulmonary arterial pressures at rest and during exercise, and the pulmonary "capillary" pressure. It is our opinion, however, that the information obtained from cardiac catheterization is of limited value in the determination of whether a tight mitral stenosis is present. Where the diagnosis is in doubt before catheterization, it is rarely made by catheterization.

Cardiac Output.—The resting cardiac output and cardiac index are decreased, often markedly so, in tight mitral stenosis. The average cardiac index in our patients was 2.05. Inasmuch as two factors, the mitral stenosis and cardiac decompensation, may play a role in decreasing cardiac output, the relative importance of each factor must be assessed in any given case. When the heart is of nearly normal size and cardiac decompensation is not present to a significant degree, the cardiac output may reflect the severity of the mitral stenosis.

The resting cardiac output in patients with mitral insufficiency is also reduced and has in fact been reported to be lower than in those with mitral stenosis.[8] However, decrease in cardiac output due to cardiac decompensation may have been involved.

These patients show an inability to increase significantly the cardiac output during exercise. Whatever increase does result is due to a decided elevation of pulmonary arterial pressure. Tachycardia, by decreasing the diastolic filling period, tends to decrease the cardiac output. This effect may outweigh the effect of increased pulmonary arterial pressure, resulting in a decreased output during exercise. Inability to increase cardiac output is also present in patients with mitral insufficiency and in patients with cardiac decompensation due to other causes.

Pulmonary Arterial Pressure.—The pulmonary arterial pressure is usually increased at rest but may be within normal limits even in the presence of tight mitral stenosis with diminished cardiac output. Apparently patients show various methods of compensating for their handicap; in some the output is maintained by raising of the pulmonary arterial pressure, while others manage surprisingly well on very low cardiac outputs and low pulmonary arterial pressures.

The pulmonary arterial pressure rises rapidly and severely with slight exertion, the systolic pressure frequently doubling. The pressure increases shown in column 15 in table 1 resulted from exertion that was usually very mild, because of the functional status of the patients. An increase in pulmonary arterial pressure during exertion occurs in the presence of various cardiac conditions and is not diagnostic of mitral stenosis.

Pulmonary "Capillary" Pressure.—When the tip of the catheter is advanced through the pulmonary arterial tree until it occludes a branch, the pressure that may then be recorded has been shown to be a close approximation of the pulmonary capillary pressure.[9] This pressure also bears a definite relationship to left auricular and pulmonary venous pressures. Evidence of mitral regurgitation when this is severe may at times be seen in the pulmonary "capillary" pressure tracing. Such evidence would be of value in excluding the diagnosis of tight mitral stenosis.

Calculation of Mitral Valve Area by Formulas.—Gorlin and Gorlin have presented a formula for calculation of the mitral valve area in cases of mitral stenosis.[7] This formula states that the mitral valve area in square centimeters is equal to

$$\frac{\text{mitral valve flow in cubic centimeters per second}}{31\sqrt{\text{"PC"} - 5}}$$

where "PC" is the pulmonary "capillary" pressure. Mitral valve flow in cubic centimeters per second is calculated by dividing the cardiac output in cubic centimeters per minute by the diastolic filling period in seconds per minute. The diastolic filling period is estimated from the brachial arterial pressure-pulse contours. These authors find that the valve areas calculated from this formula correlate very well with the valve areas found at operation or autopsy.

---

[7] Gorlin, R., and Gorlin, S. G.: Hydraulic Formula for Calculation of the Area of the Stenotic Mitral Valve, Other Cardiac Valves, and Central Circulatory Shunts, Am. Heart J. 41: 1 (Jan.) 1951.

[8] Draper, A., and others: Physiologic Studies in Mitral Valvular Disease, Circulation 3: 531 (April) 1951.

[9] Hellems, H. K.; Haynes, F. W., and Dexter, L.: Pulmonary "Capillary" Pressure in Man, J. Appl. Physiol. 2: 24 (July) 1949.

To derive their formula, Gorlin and Gorlin made a number of assumptions, some of which probably introduce little error, while others may introduce errors of a magnitude sufficiently great to make the formula of questionable value. By assuming a fixed value for "PC" and using cardiac output instead of mitral valve flow, a simplified formula may be derived that requires only the resting cardiac output. Thus,

$$\text{mitral valve area} = \frac{8 + (\text{C.O.} - 3)\,5}{14}$$

where C.O. is resting cardiac output in liters per minute.

In six of our patients in whom the pulmonary "capillary" pressure was determined, the mitral valve areas by the formula of Gorlin and Gorlin were calculated as 0.5, 0.7, 0.7, 0.9, 0.6, and 0.8 sq. cm. With the use of the simplified formula given above, the corresponding values were 0.5, 0.5, 0.7, 1.0, 0.4, and 0.8. The similarity is striking. Recalculating the data of Gorlin and Gorlin by means of the simplified formula given above, one finds that in 16 of their 21 cases the simplified formula gives a value within 0.2 sq. cm. of the value obtained with their formula.

The purpose of these comparisons is not to propose another formula for calculation of the mitral valve area, but rather to point out, first, that it may be incorrect to make several broad assumptions and then employ measurements that are too fine, and, second, that the important variable in the formula is apparently the cardiac output.

AMYL NITRITE AND THE VALSALVA TEST

Amyl nitrite inhalation has been suggested as a test for tight mitral stenosis. The test depends on the production of tachycardia, which, as has been mentioned, these patients tolerate poorly. Syncope will, therefore, frequently follow amyl nitrite inhalation in patients with mitral stenosis. Without other data the test, of course, means nothing. If the diagnosis is definite before the test is done, the test may be of a little value in confirmation.

decided rise in systemic arterial pressure, which lts in bradycardia, normally follows the Valsalva maneuver. This post-Valsalva hypertension depends in part on the increased venous return and cardiac output following the fall of the intrathoracic pressure to normal. Since the output of the left ventricle cannot increase to any degree in patients with tight mitral stenosis, the rise in arterial pressure and the resulting bradycardia do not occur or tend to be less pronounced. The Valsalva maneuver has therefore been suggested as a test for tight mitral stenosis.[10] Further study has shown that post-Valsalva failure of the arterial pressure to increase and failure of bradycardia to develop may be seen in other conditions and that the test has no great or specific value.

SUMMARY

The diagnosis of tight mitral stenosis can be made clinically on the basis of the following findings:

1. The presence of the typical diastolic murmur of mitral stenosis. This murmur is usually loud or moderately loud but may occasionally be faint.

2. The absence of a loud apical systolic murmur, indicative of mitral insufficiency. A faint systolic murmur is frequently present, and occasionally there may be a moderately loud systolic murmur.

3. The presence of an enlarged left atrium. This is usually evident on fluoroscopic or roentgenographic examination. It is also evident in the electrocardiogram as a change in the P waves or by the presence of auricular fibrillation.

4. The absence of left ventricular enlargement. This is determined by the fluoroscopy and roentgenogram. The absence of a horizontal electrocardiographic position of the heart and left axis deviation is corroborative. In the presence of a significant aortic valvular lesion or longstanding hypertension, there may be some left ventricular enlargement.

In the presence of the above findings, valuable corroborative findings are (1) a functional status of class 3 or 4, (2) evidence of right ventricular hypertrophy on fluoroscopic examination or in the roentgenogram or the electrocardiogram, and (3) episodes of pulmonary edema, congestive failure, or hemoptysis in the presence of a heart of only moderately increased size. Cardiac catheterization furnishes interesting data but is usually of little value in the diagnosis of tight mitral stenosis.

Presymptomatic Medicine.—Screening as a routine function of practicing physicians represents a departure in activities to which the profession as a whole has not completely oriented itself. . . . For centuries the public has looked to the medical profession for the cure of diseases and the relief of suffering, to tax-supported agencies for sanitation and preventive medicine. The search for diseases in their earliest stages is an extension of preventive medicine toward medical practice, or an extension of medical practice toward preventive medicine—dependent upon viewpoint. It represents a new form of activity which might be termed "diagnostic preventive medicine," "preventive diagnosis," or "presymptomatic medicine." The field of presymptomatic medicine has not been sharply delineated as a practical challenge for physicians. . . .

Adequate "screening" by the medical profession has been hampered (*a*) by the traditional role of physicians as healers, (*b*) by economic factors, (*c*) by lack of interest in the "well patient," (*d*) by the low yield of mass screening technics, (*e*) by the faulty logic of medical professors who have engendered confusion between "screening" and the diagnosis of a presenting complaint, and (*f*) by the let-George-do-it philosophy of therapeutic specialists. If "screening" is to be carried out in routine medical practice, the entire profession must face the issue, and each physician must be prepared to carry his share of the burden. Moreover, it is essential that the medical profession as a whole develop a new attitude toward each patient, (*a*) as an individual with a chief complaint, and (*b*) as a person to be "screened" for unsuspected chronic diseases. In his time-honored role as healer the physician must listen intently to the chief complaint of the sufferer and take whatever steps historical, physical or laboratory are required to arrive at the proper diagnosis. As a practitioner of presymptomatic medicine he must carry out such additional steps as are needed to exclude a reasonable likelihood of the existence of any threatening entity.—Benjamin V. White, M.D., Practical Diagnosis in Preventive Geriatrics, *Geriatrics*, April, 1952.

COMMISSUROTOMY FOR MITRAL STENOSIS

TECHNIQUE FOR PREVENTION OF CEREBRAL COMPLICATIONS

Charles P. Bailey, M.D., Axel K. Olsen, M.D., Kenneth K. Keown, M.D., Henry T. Nichols, M.D.
and
William L. Jamison, M.D., Philadelphia

One of the most tragic complications occurring in a case of mitral stenosis is cerebral embolization. In those cases in which the condition does not prove fatal, there is usually a long period of invalidism and not infrequently a permanent residual paralysis or personality change. With present generally accepted medical management, such vascular accidents are not completely avoidable, especially in cases with associated auricular fibrillation. The daily use of anticoagulants such as bishydroxycoumarin (dicumarol®) to maintain a persistent state of relative incoagulability of the circulating blood is an incomplete and none too satisfactory method of protection against embolization in cases of mitral stenosis. The patient is thereby converted into a "bleeder," with the constant risk of serious hemorrhage should he sustain a slight wound from any cause.

Logically, the best protective measure against the formation of auricular thrombi and the occurrence of embolization is the early surgical attack on the ultimate causal factor, mitral stenosis. Operation in the early stages of the disease would eliminate the possibility of blood stagnation, and the common site of thrombus formation, the atrial appendage, would be obliterated. There will probably be a considerable lapse of time before the medical profession generally accepts the philosophy of aggressive surgical attack in what has formerly been considered a chronic medical illness. Until the time comes when early surgery is universally accepted, we shall continue to have the problem of the thrombosed auricular appendage and its resulting emboli and must continue in our efforts to solve it by presently acceptable means.

Theoretically, amputation or ligation of the thrombosed auricular appendage would prevent peripheral emboli. Experimentally, this was proved to be an adequate solution by Hellerstein, Sinaiko, and Dolgin.[1] To us, this solution appears to be an oversimplification. While the majority of fresh, soft thrombi are located entirely within the left auricular appendage, there are many cases in which long streamers or eel-like extensions of the thrombi extend well into the main auricular cavity. These could easily be dislodged during ligation or amputation of the auricular appendage. The commoner type of thrombus encountered in the auricular appendage at operation is firm, well organized, and attached securely to the trabeculae and to other irregularities within the lumen. It is not unusual in such cases to find an extension of this organized thrombus in the form of a large flat mass, coating or lining the lateral wall of the auricle to which it is firmly adherent. The entire thrombus then assumes the shape of a mushroom, with the stem in the auricular appendage. While it would appear unlikely that embolization could be produced by such an old well-organized thrombus, auricular appendectomy has been practiced for such. In some cases a considerable portion of the auricular lumen is filled with a large thrombus, perhaps poorly organized (fig. 1).

When arterial embolization occurs during the course of medical treatment of mitral stenosis, it is generally accepted as unavoidable by the patient, the family, and the physician. However, when it occurs during or immediately after commissurotomy, it is inevitably and correctly attributed to surgical intervention. Commissurotomy can never attain general and complete acceptance until this complication is largely eliminated.

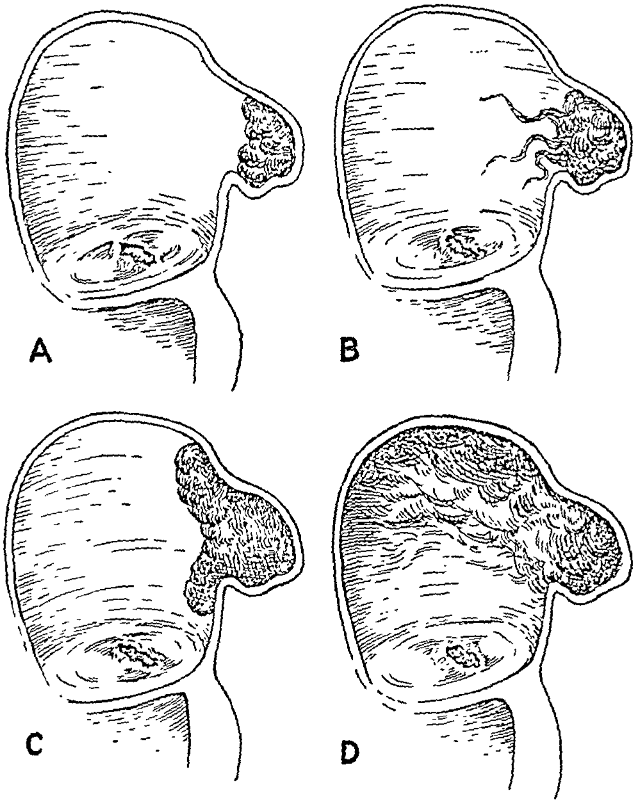

Fig. 1.—Thrombosis of the auricular appendage. *A*, limited to the appendage. *B*, associated with eel-like streamers of thrombus floating in the true auricular cavity. *C*, mushroom-like thrombus of appendage with cap lining the auricular wall (usually well organized). *D*, extensive intra-auricular thrombosis with varying degrees of organization.

While a large portion of arterial emboli occurring during medical treatment for mitral stenosis lodge in vessels of the extremities and abdominal viscera, we have seen no such localization occur in a series of 235 surgically treated patients. However, we know of several cases of arterial embolization to the lower extremities or to the bifurcation of the aorta occurring in the practice of other operators during the performance of commissurotomy.

---

[1] Hellerstein, H. K.; Sinaiko, E. S., and Dolgin, M.: Amputation of Canine Atrial Appendages, Proc. Soc. Exper. Biol. & Med. 66:337 (Nov.) 1947.

This complication is evidently less common than cerebral embolism occurring during surgery, is a less serious threat to life and health, and is more easily treated. In this series, there were 12 instances of cerebral embolization. We do not wish to imply that most emboli released during the maneuvers of commissurotomy fail to traverse the aortic arch to enter the vessels beyond. Rather, we think that many of the probably more frequent emboli that do pass the aortic arch are of such small size that they usually remain unnoticed when they lodge peripherally. Particles of the same size coming to rest in the cerebral arterial pathways quickly make their effects evident.

It should be mentioned that thrombotic material in the atrium or its appendage is not the only source of these emboli. Some of them may be small pieces of calcium dislodged from the valve during commissurotomy. This calcium may exist as loosely attached sand-like fragments on the edges of the valve orifice, as a block-like mass at either commissure, or as a general infiltration of the valve substance. We feel that such calcium fragments were responsible for the embolism in at least two cases in this series. In one, the calcium was actually demonstrated in a cerebral artery at autopsy (fig. 2). Our difficulties because of cerebral embolization, occurring in 5.1% of 235 cases in which commissurotomy was done and contributing to a sizable proportion of our mortality and morbidity, have led us to undertake a study of the problem in regard to its avoidance and treatment.

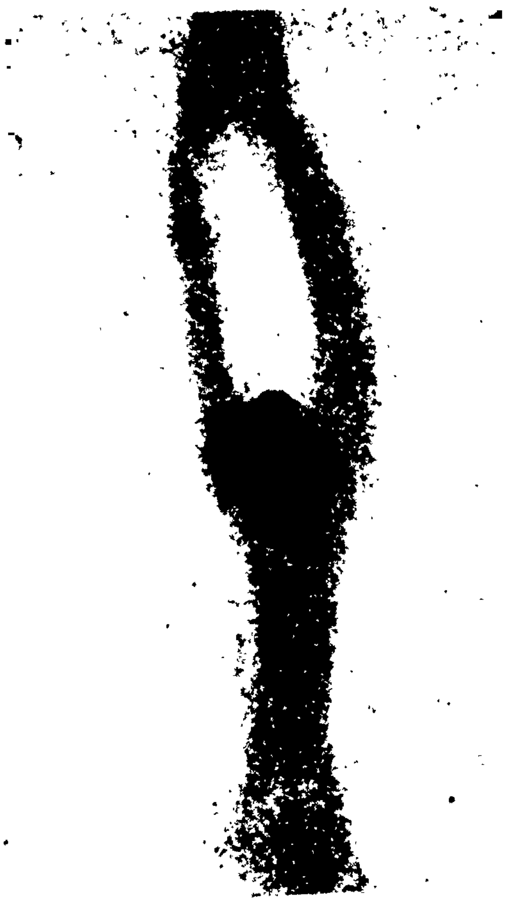

Fig. 2.—Cerebral embolism due to dislodgment of a bit of calicification from the stenotic valve orifice. Roentgenographic demonstration of calcium in brain post mortem (enlarged 4.7 diameters).

Of the 12 patients with this complication, 5 presented evidence of predominant involvement of the right side of the brain and 7 of the left. Three had bilateral involvement. All 12 patients presented definite neurological changes indicative of cerebral embolism, although 6 did not regain full consciousness postoperatively. The majority had signs and symptoms that suggested involvement of the middle cerebral artery or its branches. There was hemiplegia in nine cases and partial quadriplegia in three. There were eight deaths among the 12 cases, a mortality of 66.6%. In each case, we felt that death was directly related to this complication.

LOCALIZATION

The localization of the cerebral involvement corresponds essentially to that disclosed experimentally by Cone and Barrera.[2] The reason for this frequent involvement is not explained but may be assumed to be due to the more direct flow of blood into the middle cerebral artery than into the anterior or posterior artery. An embolus floating into the vertebral artery, if small, might well pass into one of the many branches of the basilar end and cause no trouble. If large enough to occlude the vertebral or basilar artery, death would rapidly ensue.

PATHOLOGICAL CHANGES

The pathological changes in the brains of the patients who were examined post mortem were extensive areas of softening with small hemorrhages interspersed. In no patient had the hemorrhagic areas coalesced to form a large discrete hematoma. The portion of brain involved in these middle cerebral emboli was typical. It demonstrated the reason for the more pronounced involvement of the arm, and, when the dominant hemisphere was affected, for the severe speech disturbance.

SYMPTOMS AND SIGNS

From a review of the anesthesia records we found that, during the course of surgery and anesthesia, the only early positive finding suggesting the incidence of cerebral embolization was a severe drop in systolic and diastolic blood pressures that rapidly (in 5 to 10 minutes) returned to a normal value for the patient during surgery.

It was the aim of the anesthesiologist to have the patients sufficiently awake at the completion of surgery so that simple commands for movement of the extremities might be obeyed. Therefore, prolongation of the unconscious state immediately after surgery, partial or complete paresis, aphasia, and pathological reflexes (Babinski sign and ankle clonus) were used for the clinical diagnosis of cerebral embolization. When seen shortly thereafter by the neurosurgeon, the patient usually had flaccid hemiplegia, with no motion in the arm and only flexor reflexes in the leg on painful stimulation. There was usually pronounced central facial weakness.

The diagnosis was established clinically in all cases. In three (25%), a spinal puncture was done to rule out the presence of intracranial bleeding. The pressure was found to be at the upper limits of normal. Death occurred in one case within five hours, and in the remaining fatal cases the patient survived 1, 1, 2, 5, 8, 40, and 53 days, respectively. In the last case, terminal subacute bacterial endocarditis developed.

Among the four patients who recovered, none became completely well. The use of the leg became essentially normal in all. The arm was definitely impaired, but still partially useful in all. The speech function became adequate, but impaired, in three. The fourth patient at no time exhibited aphasia (left-sided paresis).

Our therapeutic efforts consisted, in the main, of the use of stellate ganglion blocks. Systemic heparinization was also carried out in one case, but the patient succumbed in 30 hours owing to rupture of a fulminating ulcer of the stomach. This case is to be reported in detail elsewhere.[3] The thought was entertained that it might be possible to pass a small catheter up the internal carotid artery and through it to aspirate the obstructing material. This proved impractical by cadaver studies, because of the S-shaped curve of the vessel before it communicates with the circle of Willis. It was further interdicted by the demonstration of Harvey and Rasmussen [4] that 30 minutes of ischemia produces irreparable brain damage.

Stellate ganglion blocks [5] were done if the patient was (1) unable to move all extremities, (2) aphasic, or (3) unconscious and unable to respond to painful stimuli. Either the anterior approach of Ochsner and DeBakey [6] or the anterolateral technique of Volpitto and Risteen [7] was used in each case. Horner's syndrome and/or warming of the upper extremity of the side on which the injection was made (opposite to the side of the paresis) constituted evidence of a satisfactory block. It became apparent early that, for adequate inhibition of sympathetic impulses from the stellate ganglion, the block would have to be repeated every two to four hours. To simplify the procedure, we adopted the following techniques.[8] A no. 15 Tuohy needle was inserted in the proper position, and through it a no. 4 radiopaque urethral catheter with stylet was threaded until it met resistance. The needle was then removed, leaving in place the catheter, which was secured by narrow strips of adhesive or by nonabsorbable suture. After removal of the stylet, a blunt no. 23 Leur-Lok needle was inserted into the distal end of the catheter. Five cubic centimeters of 1% intracaine® (beta-diethylaminoethyl-*p*-ethoxy benzoate hydrochloride) solution was then injected.

If a Horner's syndrome was not obtained within five minutes, administration of the dose was repeated. Failure of the second injection to inhibit sympathetic activity called for a bedside roentgenogram so that we might determine whether the catheter tip was in the proper position. If not, it was withdrawn and reinserted in the same manner and a roentgenogram was again taken. If the position was satisfactory, a three-way stopcock was attached to the no. 23 Leur-Lok needle. Connected to the stopcock were a flask containing 1% intracaine® and a 10 cc. Leur-Lok syringe. This allowed withdrawal of 5 to 10 cc. of the solution into the syringe for injection through the catheter every two to four hours as required to maintain the desired effect.

In addition to the ganglion blocks, an occasional dehydration regimen, mild sedation, and vasodilators were used. Eight of the patients were treated by stellate ganglion block on the side of the cerebral lesion. Two patients received one such block, four received multiple blocks at intervals of two to four hours, and two received continuous block. The mortality in the group treated by block was 62.5%, and that of the untreated group was 75%. However, it was our clinical impression that more rapid and satisfactory recovery from paralysis occurred in those treated by block than in those not so treated. It was obvious, nevertheless, that this form of therapy was not satisfactory, and our attention was therefore turned to the possible prevention of the complication.

PREVENTIVE MEASURES

Since most of the emboli were presumed to be related to dislodgment of the thrombotic material in the auricular appendage as the operator's finger was inserted into the left auricle, an attempt was first made to recognize thrombosis of the appendage before insertion of the finger. Then we thought it possible, after carefully clamping the appendageal base, to remove the thrombus from the excluded appendageal lumen. By intermittently releasing the basal clamp, we would provide a rapid gush of blood to expel any residual bits of loosened material. This technique has at times seemed to be highly effective. However, it is open to the objection that the clot may initially extend well into the auricular cavity and may, therefore, be divided by the pressure of the basal clamp. Also, some thrombi are completely or partially organized and well attached, so that they are not easily or completely extractable from the appendage or auricle. Having observed cerebral embolism develop in two patients when thrombi had apparently been completely removed from the appendage, we reluctantly abandoned this technique. We now feel that it is often impossible to recognize thrombosis in the auricular appendage before opening the structure.

Our next attempt was to devise an entrance into the left auricle that would avoid the thrombosed appendage. Such possible sites of entrance are provided by an incision in the auricular wall itself or by an incision in the wall of the left superior pulmonary vein. Entrance through the auricular wall, even though guarded by a purse-string suture about the area, carries the inherent risk of uncontrollable hemorrhage. The sometimes friable auricular wall may be easily lacerated by a too tight purse-string or mattress suture. Therefore, we have used this approach on only three occasions, fortunately without serious incident.

Entrance into the left auricle by way of the left superior pulmonary vein has been used on 21 occasions. There have been two deaths in this series, both of which could be considered as due to the choice of this method of entering the heart. This represents a mortality of 9.5%. While all 21 patients presented gross thrombosis of the auricular appendage and presumably would have had a high incidence of cerebral embolization, it is questionable whether we can justify entrance via the vein on the basis of these statistics. However, both deaths occurred relatively early in our use of vein approaches, and it is noteworthy that there were no instances of brain embolism in this series, in which there was undoubted predisposition to embolism.

The disadvantages of the auricular approach via the left superior pulmonary vein may be summarized as follows.

1. The finger is 2 to 4 cm. farther from the mitral valve than when entrance is effected through the auricle. This makes both the digital pressure technique and instrumental division of the valve technically more difficult and more likely to be imperfectly performed.

2. The vein is often insufficiently large to admit the average operator's finger, requiring extension of the vein incision partially into the auricular wall. Otherwise the vein may be torn partially away from the auricle, resulting in serious hemorrhage and great difficulty in restoration of the vascular continuity.

3. Hemorrhage about the finger, or about the finger and instrument, and after removal of the finger from the heart, may be difficult to control. It may be managed by the use of a purse-string suture in the auricular wall or by a curved Potts-type clamp applied to the side of the auricle, or by both. The former puckers the auricle so much that it makes reparative suturing difficult. The clamp may lacerate the usually somewhat friable auricular wall. At times bleeding may be controlled by manually pinching the vein.

4. Thrombosis of the pulmonary vein beginning at the suture line may lead to hepatization of the upper lobe of the left lung and to death from what clinically appears to be pulmonary edema. This occurred only once in our series, when the pulmonary vein was incised transversely. The lumen of the vein was markedly diminished by the constricting effect of the sutures. Since using a longitudinal incision, we have had no more difficulty of this type.

5. Temporary obstruction of the blood return from the upper lobe (or from the entire left lung when only a single left pulmonary vein exists) may precipitate cardiac standstill in a borderline case. The difficulties of performing cardiac massage and resuscitation are greatly increased when there is a clamp on the side of the auricle.

In spite of these objections, we have continued to use this means of approach to the left auricular lumen and expect to continue to do so in certain cases. An example would be the case in which thrombosis and organization have taken place in the distant past, resulting in extreme contracture and near obliteration of the appendage. It is impossible to insert the index finger through such a diminutive structure. It is possible, at least theoretically, to avoid embolism of thrombotic origin to all locations, both cerebral and peripheral, by entrance through a pulmonary vein.

When it is deemed necessary to utilize the pulmonary vein to enter the left auricle, the left pulmonary drainage is inspected. Sometimes a single large vein drains the entire left lung. Technically such a single large vein affords an ideal entrance into the heart, but it also requires cutting off the entire blood return from the left lung during the period of clamping. Usually the pulmonary veins enter the auricle separately, and its accessibility commends the superior one for our use.

TECHNIQUE OF COMMISSUROTOMY VIA LEFT SUPERIOR PULMONARY VEIN

The chosen vein is carefully mobilized within the pericardium. A purse-string suture of no. 2 braided silk on an atraumatic curved needle is placed in the auricular wall about the base of the vein. It is wise to have the extremities of the purse-string emerge from the auricular wall at its most accessible aspect (laterally) and at about 1 cm. from the vein insertion. This permits one to extend the vein incision for a distance into the true auricular wall if the vein lumen is insufficient to permit complete insertion of the operator's index finger. The purse-string is now passed through a Rumel-Belmont tourniquet to permit flexible, reliable hemostatic control.

A Potts' ductus clamp, preferably of the angulated variety, is now applied across the distal extremity of the vein. A half-curved Potts' clamp is placed on the auricular wall proximal to the vein. A 2 cm. incision is made longitudinally in the most accessible wall of the vessel, extending, if necessary, for a distance into the auricular wall. A bistoury type of knife blade and a pair of angulated iris scissors are ideal for opening the vein.

The two lips of the vein incision are picked up with fine thumb forceps, and the tip of the operator's double-gloved right index finger is engaged in the opening. As the proximal clamp is released, the finger is quickly inserted into the left auricle and the purse-string is tightened sufficiently to control bleeding.

The auricle and especially the internal opening of the appendage are explored for thrombi. If any are felt, they are carefully avoided. In three instances we have felt eel-like streamers of evidently very friable thrombi protruding from the appendage into the auricular lumen. In four cases there was extensive intra-auricular thrombosis, with a large portion of the chamber filled by incompletely adherent soft clots. In one case an attempt to remove the thrombi proved fatal (from hemorrhage). In the other three, they were ignored; they produced no subsequent symptoms.

The valve is explored and commissurotomy is performed by digital pressure alone whenever possible. The digital method was used alone in 10 cases of our series. The remaining 11 valves required instrumental division. When an instrument is employed, great technical difficulties may be encountered and bleeding is likely to be serious, because the necessary mechanical maneuvers often distort the vein orifice, owing to the disadvantageous site of entrance and the increased distance from the valve.

When the definitive work is completed, the finger is withdrawn from the heart and vein and the auricle is reclamped for hemostasis. The vein is flushed with dilute heparin solution, and the lips of the incision are approximated by a continuous suture of 5-0 arterial silk on a curved needle. We usually run it as an everting mattress suture from one extremity of the incision to the other and then reverse the suture, using a more superficial running stitch to approximate the adventitia. The terminal end of the suture can then be conveniently tied to the original end. If the vascular incision has invaded the auricular wall, it is well to place a single mattress suture of heavier material at this point.

After release of the clamps, pulmonary vein flow is resumed. There should be minimal bleeding. The pursestring suture may be tightened at any time if the clamp fails to provide adequate hemostasis. This suture should be removed or at least divided after vascular continuity has been restored.

After a sizable experience with the technical and potential difficulties and dangers associated with the approach to the valve via the superior pulmonary vein, we became satisfied that it did not provide a completely satisfactory answer to the problem of cerebral embolization during commissurotomy. Part of this dissatisfaction stemmed from a realization that emboli might originate from calcium deposition on the valve itself. Another unsatisfactory feature was the difficulty noted in recognizing minor degrees of thrombosis in the auricular appendage until after it had been actually clamped and opened. We felt that there was appreciable danger of the damage having already occurred by the time this stage of the operation had been reached. Slight to extensive thrombosis of the appendage had occurred in 35.5% of 200 cases of commissurotomy reported elsewhere.[9] In only about half of these was the condition recognized prior to opening of the appendageal lumen.

It appeared that it would be impossible, at least on many occasions, to prevent the entrance of free particulate matter into the systemic circulation during the course of a commissurotomy. There would thus always be danger that these particules might enter the carotid arteries and produce cerebral embolization. The only satisfactory answer seemed to lie in the direction of "straining" the blood entering these vessels or of obstructing them during the strategic periods when the particles might enter the aorta. "Straining" the blood seemed impractical, so that attempts were made to occlude the vessels.

It occurred to us that, by simply squeezing the patient's neck very tightly for periods up to 60 seconds at the *strategic moments* (such as during clamping of the appendage, inserting the finger into the heart, and dividing the calcified valve), we might greatly slow the flow of blood through the carotid arteries. Then the possible emboli would undoubtedly pass by the mouths of these vessels and produce their effects, if any, in the upper extremities or in the lower portions of the body. This hope proved to be vain. There were two cerebral emboli in nine patients subjected to such external cervical pressure. In addition, another patient seemed in danger of cardiac standstill, presumably as a result of the attendant carotid sinus reflex simultaneously produced.

Finally, it was deemed necessary to actually mobilize the root of the innominate and left common carotid arteries in the mediastinum to permit transient occlusion of their circulation. On the counsel of one of us (A. K. O.) and in view of the experiences of Hamby,[10] it was deemed reasonable to completely prevent blood flow through the innominate artery for a period of up to 20 minutes, during which time the definitive valvular operation should certainly have been accomplished. Such innominate occlusion would seem surely to prevent any possibility of embolization to the right side of the brain (the site of embolism in five, or 41.6%, of our series).

Courville[11] has shown that the brain can tolerate oxygen want, and Stokes and Gibbon[12] have shown that it can tolerate complete cessation of circulation for periods of up to three minutes. It was, therefore, deemed safe simultaneously to occlude temporarily the left common carotid artery at its origin for periods of up to 60 seconds. This could be done at each strategic period of manipulation, with reliance on the cardiac contractions to evacuate all free particulate matter from the heart and the aortic arch within 20 to 60 seconds of dislodgment. This would afford a considerable degree of protection to the left side of the brain.

We found we could easily accomplish this intermittent obstruction to the left common carotid artery by kinking it with an umbilical tape applied around it near its origin. It takes little traction to kink the left common carotid in the average person. It was felt best to leave the left subclavian artery unoccluded. It provides a certain amount of the cerebral circulation by way of the left vertebral artery and, therefore, would tend to prevent the more serious features of cerebral anoxemia from appearing. Should a small embolus enter the left vertebral artery, it would seem unlikely to appreciably interfere with the cerebral circulation, since there is extensive collateral circulation at the termination of this vessel and of the basilar artery (*fig. 3*).

TECHNIQUE OF PROTECTIVE CAROTID OBSTRUCTION

The technique we have worked out to apply this principle is as follows: A left lateral approach is used as usual. The fourth rather than the fifth intercostal space is chosen for entrance into the thorax, because it affords greater accessibility to the upper mediastinum. The lung is compressed downward, and the mediastinal pleura is opened longitudinally above the aortic arch between the left vagus and the left phrenic nerves. By blunt dissection, the left common carotid artery is mobilized at its origin. An umbilical tape is passed underneath it, and tentative traction is made so that the operator can determine the ease of kinking off its lumen (fig. 4).

In most instances the innominate artery is found to be more deeply located within the mediastinal tissues and to lie just anterior to the left common carotid. Occasionally it lies far enough anteriorly to require mediastinal dissection anterior to the left phrenic nerve. A silk suture is placed under it with a ligature carrier or gallbladder clamp but is not tied. Further mobilization and traction on this suture permits a noncrushing clamp to be placed across the origin of the vessel. We prefer to use a bulldog clamp of the Beck or Potts' type. Disappearance of the right radial and temporal pulse indicates complete occlusion (fig. 5). The innominate artery is kept obstructed during the entire period of definitive intracardiac surgery. This is usually less than 20 minutes but in one case was 34 minutes.

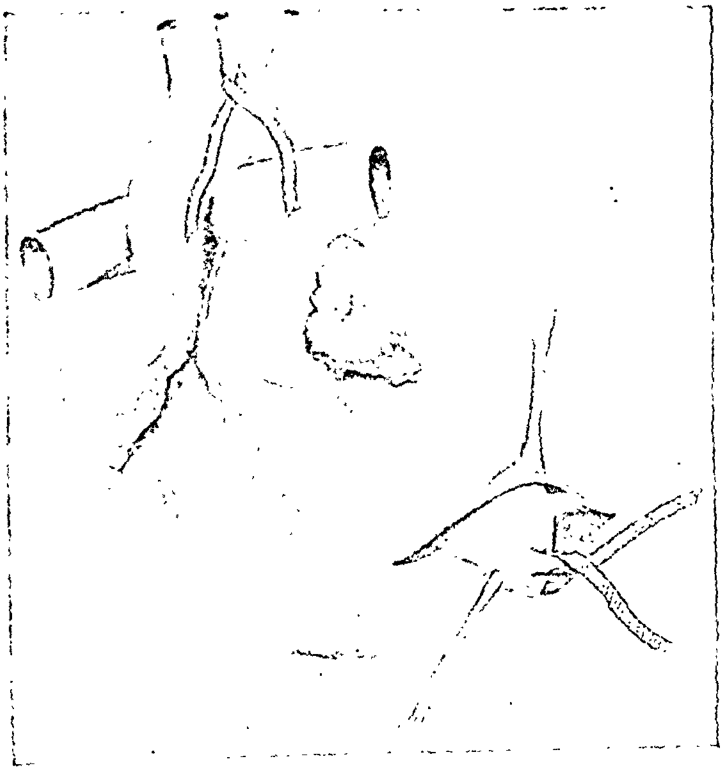

Fig. 4.—Umbilical tape about origin of the left common carotid artery for intermittent traction occlusion of blood flow at the strategic periods of the operation. Kinking of the vessel is carried out for periods of 30 to 60 seconds whenever it is felt likely that free particulate matter may be released into the blood stream.

The upper pericardium is then opened just posterior to and parallel with the left phrenic nerve. A purse-string suture of heavy braided silk is placed in the epicardium about the base of the appendage and is connected with a Rumel-Belmont tourniquet. If the appendage requires much mobilization or manipulation, the tape about the left common carotid may be drawn on for 30 to 60 seconds to permit safe evacuation of any inadvertently dislodged clots.

As a Satinsky clamp is applied across the base of the appendage, traction is again made on the carotid artery. The appendage is then opened and inspected for clots. They may be surgically evacuated if present. Then the operator's finger is inserted into the heart, and simultaneously traction is again made on the carotid for 30 to 60 seconds. Such carotid traction is repeated whenever the valve is examined or manipulated, if it is felt that any loosely attached calcium, vegetations, or clots are present. When a calcified valve is divided by either digital or instrumental means, traction is again made. Finally, as the finger leaves the heart and the appendage is tied the vessel is again occluded for a period estimated to be long enough to clear completely the heart and aortic arch of any loose particulate material. After the appendage is closed, the bulldog clamp is removed from the innominate artery and the suture and umbilical tape are cut and extracted. The operation is then terminated in the usual way, without any suturing of the mediastinum.

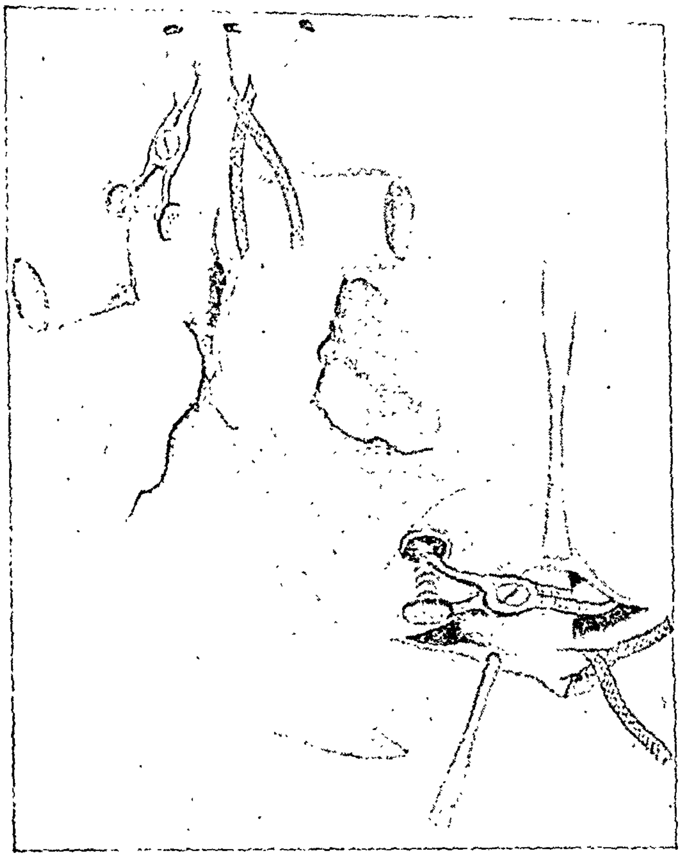

Fig. 5.—Bulldog clamp placed across the origin of the innominate artery to block its flow during the entire period of definitive intracardiac surgery. This should afford complete protection from embolization to the right side of the brain.

COMMENT

So far we have employed this type of partial obstruction to the cerebral blood flow in 80 patients undergoing mitral commissurotomy. In 26 of them, the appendage was grossly thrombosed. There have been no instances of cerebral embolization in this series. Neither have there been any symptoms suggestive of cerebral ischemia. There have been no recognized peripheral emboli. The longest period of obstruction of the left common carotid in this series was two minutes. The only recognizable untoward occurrence in this series of patients was development of a left recurrent laryngeal nerve paralysis in two patients.

SUMMARY AND CONCLUSIONS

Cerebral embolization as a result of the manipulations incident to mitral commissurotomy may be lethal or may permanently incapacitate the patient. This complication occurred in 5.1% of 235 cases in which methods other than carotid obstruction were employed to protect the brain.

Stellate ganglion block, in addition to other medical measures, was found to be of relatively small benefit in the treatment of 12 patients with cerebral embolization incident to commissurotomy. Prevention of the occurrence of cerebral (and peripheral) embolization of thrombotic origin during commissurotomy is theoretically and perhaps practically possible by utilization of the left superior pulmonary vein as a site of entrance into the left auricle. However, in 21 cases with obvious thrombosis of the appendage in which this technique was employed, there were two deaths, directly related to the vein approach. Because of the added technical difficulties and inherent potential dangers, this procedure is not recommended as a routine prophylactic method, although it will continue to be useful in certain cases of auricular thrombosis.

Prevention of complications by occlusion of the innominate and left common carotid arteries as described was attempted in 80 cases, with no evidence of cerebral or peripheral emboli and no evident untoward by-effects. Although the series is small, the results, to date, suggest that this technique may afford a reasonably easy, safe, and effective method for the prevention of cerebral embolization during commissurotomy for mitral stenosis and during other operations performed within the chambers of the left heart. Perhaps it should, in the future, be routinely used in all patients subjected to commissurotomy. Results suggest that there may be effective available collateral arterial supplies to the brain, which will support its life for periods somewhat longer than required by this technique.

LOSS OF SENSE OF TASTE DUE TO METHYLTHIOURACIL THERAPY

Norman G. Schneeberg, M.D., Philadelphia

The thiouracil group of antithyroid drugs has received an extensive clinical trial in the past eight years, and their toxic effects have been amply documented. Loss of the sense of taste has been mentioned in only a single report.[1] One of the 16 patients treated with methylthiouracil by Leys complained of complete loss of taste while receiving a daily dose of 1.4 gm. Taste sensation gradually returned when the dose was reduced.

We have recently observed complete loss of the sense of taste in two patients receiving methylthiouracil. Because of the rarity of this toxic effect and its benign nature, a brief report is appended.

REPORT OF CASES

CASE 1.—A 48-year-old woman was referred by an ophthalmologist because of marked lid retraction without measurable proptosis of the eyes and persistent periorbital edema. Her history was long and complex and only those portions pertinent to the present discussion will be included. The thyroid gland was diffusely enlarged to about three times normal size. It was smooth though lobulated, firm, and easily outlined and exhibited no bruit. The pulse rate was 100 per minute and blood pressure 146/80 to 175/88. The thyroid uptake of radioactive iodine 24 hours after the oral administration of 50 μc of I^{131} was 43%. The serum protein-bound iodine was 7.4 μg per 100 cc. The basal metabolic rate was +6% and the serum cholesterol 178 mg. per 100 cc. Because of certain equivocal thyrotoxic stigmas and the high normal I^{131} uptake and protein-bound iodine level of the serum, a therapeutic trial of strong iodine (Lugol's) solution was instituted. Sufficient clinical improvement ensued to warrant extending the therapeutic trial with the administration of *methylthiouracil*, 600 mg. daily in divided doses. After 20 days of therapy, the patient reported the gradual loss of taste sensation. Within 10 more days gustatory sense was completely absent. She found food "flat" in taste and was unable to distinguish sweet, sour, salty, peppery, or bitter substances. Three weeks later she noted that the acuity of her sense of smell was somewhat dulled. She was unable to smell an onion, and customary lacrimation did not occur. Familiar odors could hardly be detected and could rarely be identified accurately. Otherwise she was clinically improved, exhibiting a weight gain of 5 lb. (2.3 kg.), reduction of pulse rate to 85 and blood pressure to 130/80, disappearance of lid lag, reduction of lid retraction, and absence of periorbital edema. There were no signs of hypothyroidism or myxedema. Cranial nerve motor and sensory function, aside from taste and smell, were intact. There was no evidence of facial palsy; the gag and corneal reflexes were normal; and phonation was unimpaired. The tongue appeared normal, showed normal motor activity, and was sensitive to touch, pain, and temperature changes. The buccal mucosa was normal. The parotid and submaxillary salivary glands and ducts revealed no abnormalities. Because the patient could no longer tolerate loss of gustatory and olfactory sensation, 5-iodo-2-thiouracil (itrumil,® Ciba Pharmaceutical Products, Inc.), 400 mg. per day, was substituted for methylthiouracil. She reported that three days after this change in medication severe pain in the thyroid region developed; the gland became more enlarged, hard, and painful; and her temperature rose to 104 F orally. Because of my absence, another physician was consulted, who made a diagnosis of acute thyroiditis. Aureomycin therapy effected a relatively rapid subsidence of the acute process. Two weeks later I examined the patient. The thyroid borders were prominent, and the gland was larger and firmer than on previous examinations. At this time, three weeks after cessation of methylthiouracil therapy, the patient was able to recognize only the taste of salt. During the ensuing two weeks, her sense of taste and smell gradually improved but was not completely normal. Food still tasted "flat," and sweet substances seemed intolerably saccharine. Six weeks after treatment with methylthiouracil was stopped, taste and smell were completely normal. The patient refused to retest the effect of methylthiouracil and continued taking iodothiouracil, with maintenance of clinical improvement and without toxic effects. The thyroid gland had returned to its original size and consistency prior to the episode when thyroiditis was diagnosed.

CASE 2.—A 39-year-old woman complained of weight loss of 22 lb. (10 kg.) in one year despite a good appetite and her usual diet, hyperhidrosis, heat intolerance, palpitation, and

The corticoid content of the urine was estimated according to the method of Heard, Sobel, and Venning,[8] which is based on the knowledge that most of the adrenal steroids have strong reducing sugar-like properties, which are imparted by the presence in the side-chain of the primary alpha ketol grouping, characteristic of fructose. All of the active hormones of the adrenal cortex have this reducing property.

Eosinophil counts were done by the method of Randolph[9] modified to stain only eosinophils. Counts were made in 0.2 mm. depth Levy counting chambers with improved Neubauer rulings. Pipettes were tested by the United States Bureau of Standards.

* Analysis of variance:
17-ketosteroids: F = 1.07, not significant.
Corticoids: F = 1.22, not significant.
Eosinophils: F = 11.95, P = 0.01-0.001, significant.
† J. H. was not available for analysis of postseizure phase.

Data for the six patients are as follows:

R. S. was 52 years old. Her first grand mal attack occurred at the age of 16 and was set off by traumatic experience. The electroencephalogram showed a very abnormal right frontal area.

L. M. was 37 years old. Her first grand mal attack occurred at the age of 3, followed by convulsions for three years. Grand mal seizures started again at the age of 18. The electroencephalogram showed a very abnormal right frontal area.

J. H. was 56 years old. Her first grand mal attack occurred at the age of 20. The electroencephalographic tracings for both frontal areas were diffusely irregular.

M. S. was 30 years old. Her first grand mal seizure occurred at the age of 16. Electroencephalographic tracings were diffusely irregular.

E. B. was 34 years old. She had had grand mal attacks since the age of 12. Electroencephalographic tracings were diffusely irregular.

J. R. was 26 years old. Her first grand mal convulsion occurred at the age of 15. Electroencephalographic tracings for both frontal lobes were very irregular.

RESULTS

From the data in the accompanying table, it will be seen that the mean control excretion values for 17-ketosteroids are somewhat less than those reported in the literature for normal women in this age range.[10] It has been reported that 17-ketosteroids show a progressive decline with age.[11] Talbot and Butler[12] have estimated that a single determination of 17-ketosteroids on a 24-hour basis would give a value within 15% of the mean value obtained by repeated estimations. The variation from the mean values in this series is certainly greater than 15%. It should also be noted that there is no significant difference in the mean values of 17-ketosteroids excreted during the postseizure period in comparison with the control period (6.6 mg. per 24 hours before and 6.5 mg. per 24 hours after seizures).

A slight decrease in the excretion of reducing corticoids after seizures was observed. However, when subjected to an analysis of variance, this decrease was not statistically significant when compared with seizure-free values.

The effect of grand mal seizures on eosinophil levels is also shown in the table. It will be seen that there is a decrease in eosinophils following seizures in some cases. An analysis of variance indicated that this decrease was statistically significant. According to Rud,[3] the majority of authors agree that there is a general eosinopenia following convulsive attacks in epileptics.

COMMENT

The early work implicating the adrenal in convulsive states indicated that excessive secretion of the adrenals could, on occasion, precipitate seizures. Fischer and Fischer[13] in 1914 reported that inhalation of amyl nitrite produced convulsions in rabbits. They postulated that the capacity for convulsive reactivity in rabbits decreased with a decrease of adrenal substance. They also stated that one could increase convulsive susceptibility experimentally by causing a hyperfunction of the adrenal glands. Their work, although controversial, led to the examination of unilateral and subtotal adrenalectomy as a possible alleviating measure in cases of severe chronic grand mal epilepsy. The clinical results were equivocal.

The patients in this series exhibited an excretion pattern of 17-ketosteroids that was lower in quantity than comparable "normal" mean values for women in the same age group. The trend here would indicate that female patients with chronic epilepsy show a great deal more day to day variation in 17-ketosteroid excretion than do normal female subjects.

The failure to observe statistically significant changes in 17-ketosteroid and corticoid excretion patterns after

seizures, as compared with the seizure-free periods, indicates that adrenal cortical activity during the actual convulsive phase was not of sufficient intensity to produce changes great enough to be estimated by these two indexes of adrenal activity. However, the general eosinopenia following seizures does seem to indicate that the adrenal cortex is capable of responding to the stress of convulsive seizures with at least a "mild" activity. It would be expected that a stress such as a grand mal convulsion should be of sufficient intensity to induce changes in adrenal steroid excretion levels. Stresses of much less severity and intensity have been reported to induce changes in adrenal steroid excretion.[11]

The patients reported here had been experiencing seizures of the grand mal type for a number of years. A possible explanation for the failure to observe a urinary steroid response following seizures is that the adrenal cortex in these subjects, after years of being stimulated, may have become "conditioned" to the great number of attacks; therefore, it no longer responded to an "ordinary" stress, such as a convulsive seizure. The adrenal cortex in these patients with chronic epilepsy might simply be functioning at a very low ebb, probably only enough to maintain a slow excretion of corticoids, commensurate with the metabolic status of the subject in question.

It was noted during the course of this work that the incidence and duration of seizures increased during the menses and that patients who were maintained relatively seizure-free with diphenylhydantoin sodium and phenobarbital sodium therapy would occasionally "break through" with seizures during the menses in spite of continued medication. These and other observations suggest that, during periods of additional stress (such as the menses in female subjects), epileptics are more susceptible to convulsive seizures.

SUMMARY AND CONCLUSIONS

Women with chronic epilepsy exhibited a greater day to day variation in urinary steroid excretion than do normal female subjects of comparable age. There was no significant difference in the mean values of 17-ketosteroid and reducing corticoid values during the postseizure periods in comparison with control or seizure-free periods. There was a tendency toward eosinopenia after grand mal seizures. Patients with chronic epilepsy do not respond to convulsive stress in the same manner as nonepileptics. There is some indication that the adrenal cortex of patients with chronic epilepsy may become "conditioned" to convulsive stress.

RESULTS OF SUBTOTAL GASTRECTOMY FOR GASTRIC AND DUODENAL ULCERS SINCE 1917

Alfred A. Strauss, M.D., Siegfried F. Strauss, M.D., Arthur H. Schwartz, M.D., David D. Kram, M.D.
and
Walter W. Masur, M.D., Chicago

In 1914, when most surgeons considered gastroenterostomy the proper surgical therapy for duodenal ulcers, we devised a method for pyloric closure in this operation, using submucous fascial transplants from the fascia lata. We found that this procedure was much more difficult in an inflamed stomach with a duodenal ulcer than it had been in dogs. In a number of cases the pyloric antrum was torn so badly that, as a means to an end, we did a subtotal gastrectomy. These were our first cases of subtotal gastrectomies, and we noted that the results with this operation were much more satisfactory than they had been with a simple gastroenterostomy.

Advocating subtotal gastrectomy as the operation of choice for duodenal ulcer, we presented six such cases at a meeting of the Chicago Surgical Society in 1915. Many of our colleagues at that time opposed this operation on the principle that radical surgical treatment was not indicated for duodenal ulcer, and we did not again have the courage to do subtotal gastrectomies until 1917. The excellent results, which we have noted over a period of years from our first cases of subtotal gastrectomy, had convinced us that this was the proper operation for duodenal ulcer.

For about two years we did some Billroth 1 and Billroth 2 gastric resections, but in 1919 we began routinely to do posterior mesocolic Polya resections. We are still using this procedure at the present time, since it affords such excellent functional results. During the succeeding years, we made slight changes in technique from time to time, but we returned to our original technique of 1919, which we are following today in minute detail.

There is probably no subject in medicine or surgery that has caused more controversy than therapy for duodenal ulcer. Not only has there been a great deal of dispute between surgeons and internists as to whether a duodenal ulcer should be treated medically or surgically, but there also have been variances among surgeons as to which type of operation should be performed for duodenal ulcer. Even after subtotal gastrectomy has been decided on in preference to gastroenterostomy or a pyloroplasty, there is often disagreement among surgeons as to whether it should be an anterior mesocolic or a posterior mesocolic operation.

This article has been shortened by omission of figures 7 through 18, which will appear in the authors' reprints.

From the Stomach Group and Surgical Services of Michael Reese Hospital, Mount Sinai Hospital, and Franklin Boulevard Hospital.

that has eroded into the pancreaticoduodenal artery, and (3) the gastrojejunal ulcer that has eroded into the mesenteric vessel of the jejunum. Operation should be limited to a simple ligation of the bleeding vessels, and subtotal gastrectomy deferred until the patient is in good condition. A hemorrhage from any of these locations is usually so severe and exsanguinating that immediate surgery is indicated to stop the bleeding and save the patient's life. Bleeding ulcers in other locations of the stomach do not require such emergency measures as the hemorrhage is much less severe.

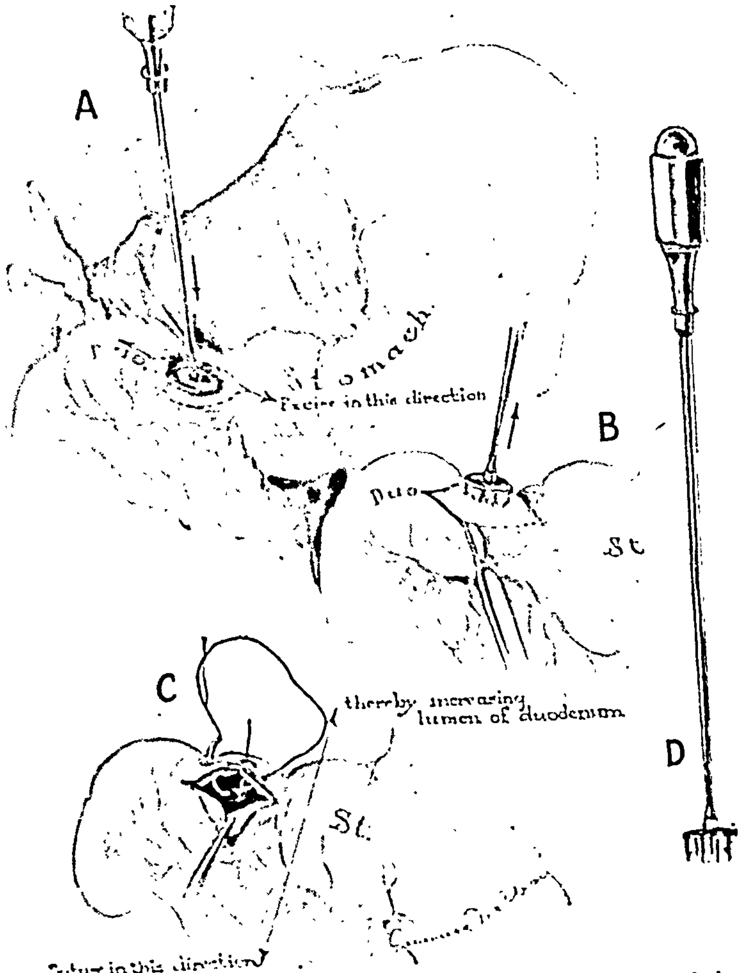

Fig. 1.—Operative procedure devised for treatment of perforated duodenal ulcer. *A* and *B*, excision through the pyloric ring into the duodenum with the perforation held in place by the fishhook spear *C*, transverse suturing of normal tissue with fine catgut and inversion wax silk suture after excision of the defect. *D*, fishhook spear devised to hold perforation in place.

PENETRATING ULCERS

Patients with acute symptoms of penetrating ulcers are kept on medical management from 10 to 14 days, when their symptoms usually subside and a subtotal gastrectomy can be done. We also treat patients with a retention from a pyloric or duodenal obstruction medically for 10 to 14 days, and institute continuous gastric suction through a Levine tube. This decreases the distention of the stomach, reestablishes its tonus, and relieves the inflammatory process in the duodenum and in the stomach wall. During this period the electrolyte balance is corrected by liberal infusions of glucose, saline, and amino acids. Several blood transfusions are also given.

TREATMENT FOR A RUPTURED DUODENAL ULCER

The ulcer area in a case of acute duodenal perforation should be widely excised, and the open area of the stomach anastomosed to the duodenum. If a gastroenterostomy is done in the presence of an acute perforation, we have found that in most of these cases a gastrojejunal ulcer forms shortly after the procedure. If a simple closure of the perforation is done and omentum is sutured over it, within six months to a year an obstructive duodenal ulcer usually occurs. For this reason, we resect a wide area around the perforated ulcer and close the defect (fig. 1). We have devised a simple instrument for this procedure (the metal fishhook type spear shown in fig. 1*D*) to hold the perforation in place. This is placed over the perforation, and forced through the muscular walls of the infiltrated areas (fig. 1*A* and *B*). A longitudinal elliptical incision is made through the pyloric ring into the duodenum. This is indicated by the dotted line in figure 1*A* and *B*. The entire area is widely excised, leaving only normal tissue, and then sutured transversely with fine catgut and a fine layer of inversion wax silk suture (fig. 1*C*). The area may be covered over with omentum. Our experience has shown us that there is a much lower percentage of recurring obstructive ulcers with this procedure than in cases in which a simple closure is done without excision of the perforated ulcer.

PATHOLOGICAL CONDITION

The chronic duodenal ulcer that is seen at surgery usually shows a marked contraction of the duodenal wall, with diverticula producing the clover-leaf deformity. The stomach is edematous and hypertrophied in appearance, and there is associated marked gastritis and duodenitis of various degrees. More than 75 to 80% of these patients have posterior wall ulcers penetrating into the head of the pancreas. The head of this organ is usually harder than normal, and slightly adherent to the pyloric ring and antrum and to the first portion of the duodenum. Th serosa of the duodenum and the hepatoduodenal lig ament are adherent and markedly thickened, and th stomach wall is also thickened in its lower third.

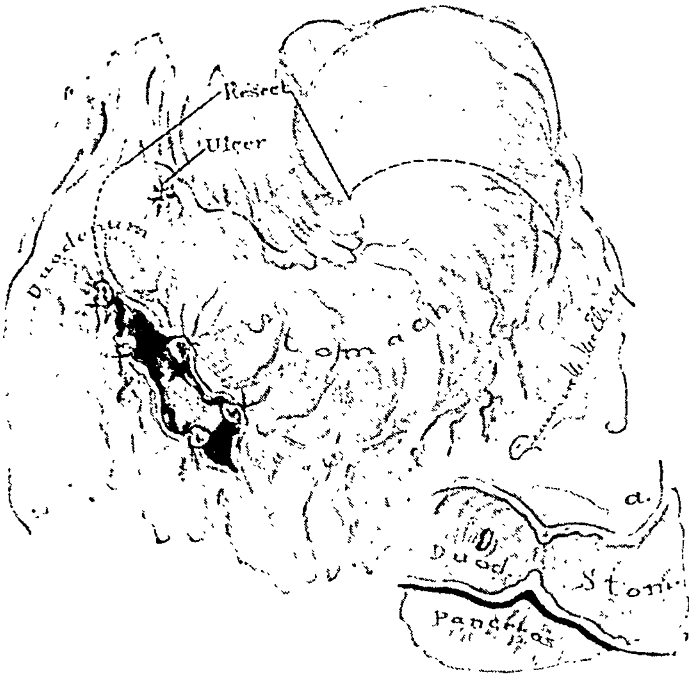

Fig. 2.—Ligation of blood supply to the greater curvature near th pylorus, and relationship of duodenal ulcer to the pyloric ring.

To achieve successful clinical end results with sul total gastrectomy, we have formulated two definite pri ciples: (1) all the pathological tissue should be remov if possible, and (2) from two-thirds to three-fourths of the stomach should be resected. We consider a rapid emptying time of 15 to 30 minutes ideal. This signifies that the stomach is only functioning from three to four times daily for 15 minutes, and is at rest the remainder of the time. We have also learned by studying the emptying time of stomachs following gastric surgery in which either a pylorectomy was done or too high a resection was performed that the stomach empties more rapidly and efficiently when three-fourths is resected. At this point it must be emphasized that the stomach varies in different persons as to size and configuration. Therefore *one has to visualize the structure in its entirety to determine* the proper level of resection.

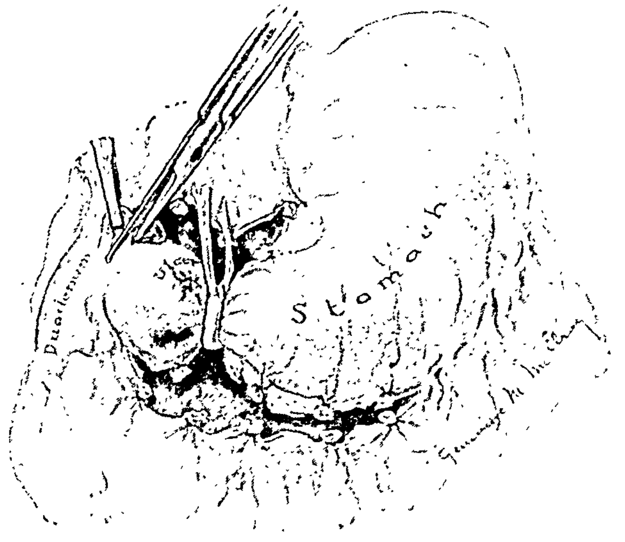

Fig. 3.—Division of anterior duodenal wall beyond the ulcer.

The various pyloroplasties, such as the Finney, Judd, Balfour, Horsley, and Heineke-Mikulicz types, have little value in therapy for duodenal ulcer, particularly for lesions that have penetrated to the pancreas. A well functioning gastroenterostomy cannot be considered as a satisfactory operation because of the high percentage of gastrojejunal ulcers occurring after this procedure. This has been reported in various clinics throughout the world, with incidences varying from 12 to 35%. In analyzing this evidence it is obvious that subtotal gastrectomy is the procedure of choice for duodenal ulcer. The mortality with this operation is very little higher than that of gastroenterostomy, and the incidence of gastrojejunal ulcers is only about 1%. Rather than subject a patient to a gastroenterostomy or another plastic operation, all of us in the gastrointestinal group would rather continue medical therapy.

SURGICAL TECHNIQUE

In doing a subtotal gastrectomy, we use a no-clamp method of the posterior Polya type. Through a median right rectus incision, the stomach is exposed. The prepyloric region is mobilized by forcing the index and middle finger through the lesser omentum along the posterior wall of the stomach. The blood vessels along the greater curvature of the stomach are clamped and ligated for about 2 in. (5 cm.) (fig. 2). The blood supply along the greater and lesser curvature of the duodenum is freed beyond the point where the duodenum is divided, which is usually just beyond the ulcer (fig. 3). A small piece of tape is tied around the pyloric end of the stomach to prevent the gastric contents from passing through the pylorus. This is tied off in place of using a clamp. The anterior wall of the duodenum is opened with a scissors below the point of the ulcer in the normal portion of the duodenum. After carefully determining its relationship to the common duct, the contents are then emptied by suction. The posterior wall of the duodenum is divided through the mucosa and the muscularis below the point of the ulcer and the contracted portion of the duodenum (fig. 4). *It is freed by sharp scalpel dissection* from the head of the pancreas where it is adherent due to penetration or perforation (fig. 5 and 6). It comes off very easily and the dissection is almost bloodless. The divided duodenum is now covered with a piece of gauze to prevent soiling (fig. 7). The inflammatory tissue resulting from penetration of the ulcer into the pancreas *is usually scraped out with a dull curette, and touched* with some tincture of iodine or thimerosal (merthiolate®) solution. This new method of dividing the duodenum below the point of the ulcer, below the point of the pathological condition, and freeing it from the head of the pancreas, is not only more rapidly accomplished but is much simpler. There is also much less danger of dividing or injuring the pancreaticoduodenal artery and the blood supply to the pancreas and duodenum. There is almost no danger of injury to the common duct, as it has been previously exposed. By dividing the duodenum below the ulcer, a free and loose duodenal wall results that can be closed as easily as a normal duodenum. We have used this technique in about 500 selected cases over a period of 10 years in preference to the older method described by us 25 years ago. *With the older technique, the* pancreas was freed away from the posterior wall of the duodenum, beginning at the pyloric end of the stomach, and dissected on down the posterior wall of the duodenum. This required more time, was more tedious, and made the closure of the duodenum much more difficult. The distal end of the duodenum is closed by inverting it with two rows of *wax silk sutures using the Connel stitch*

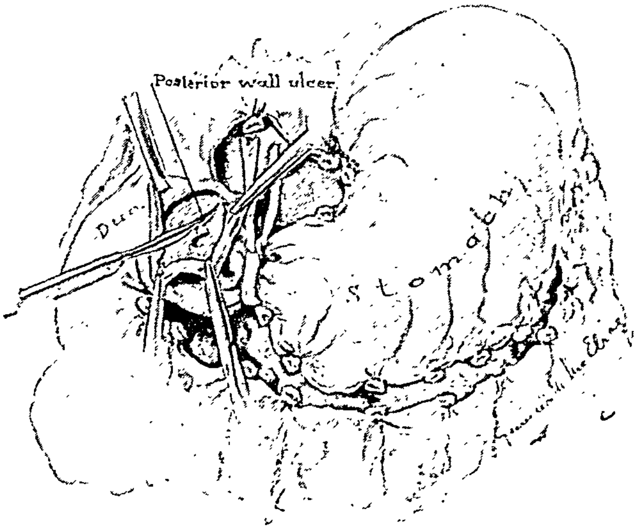

Fig. 4.—Incision of the posterior duodenal wall beyond the ulcer.

(fig. 8*A* and *B*). A third row is used to bring the lesser omentum and the capsule of the pancreas over the anterior portion of the duodenum (fig. 8*C* and *D*).

The blood vessels along the greater curvature are ligated between clamps until about 75% of the stomach is free. It is best to reach up to the cardia of the stomach to estimate and see the size of the stomach, as it varies greatly in different patients. The blood supply along the lesser curvature is divided at about the junction of the middle and upper third of the stomach (fig. 9). The mesocolon is lifted up and is split on the left side of the middle colic artery. The left half of the mesocolon is sutured with interrupted silk sutures to the posterior wall of the stomach as high up as possible (fig. 10).

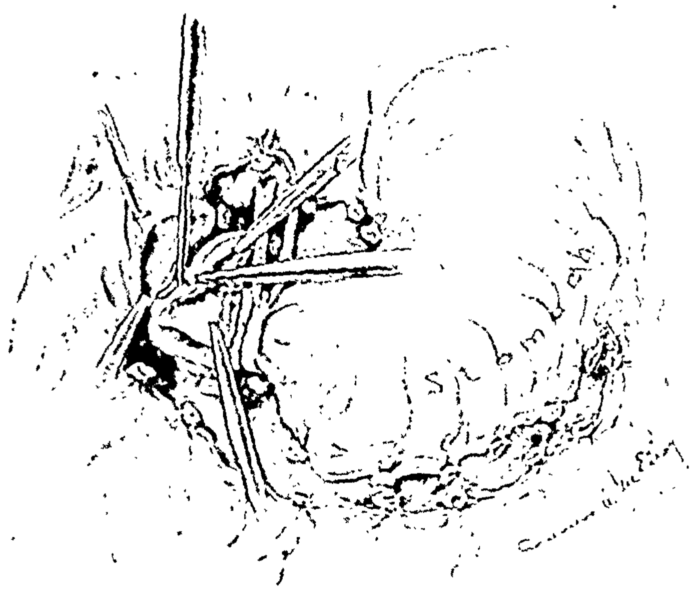

Fig. 5.—Dissection of the posterior duodenal wall from the head of the pancreas.

The first loop of jejunum as close to the ligament of Treitz as possible, usually about 1½ in. (3.8 cm.), is brought through the mesocolic slit, and sutured to the posterior wall of the stomach with continuous gastrointestinal catgut (fig. 11). The relationship of the jejunum to the remaining portion of the stomach is such that the proximal end of the jejunum is attached to the lesser curvature and the distal end to the greater curvature (fig. 11). The muscularis of the stomach and the jejunum is divided down to the submucosa about 4 mm. from the first suture line, and sutured with gastrointestinal catgut (fig. 12*A*). An opening is made through the mucosa of the posterior wall of the stomach, and the contents aspirated (fig. 12*B*). The jejunum and the posterior wall of the stomach are sutured with gastrointestinal catgut, starting at the middle of the posterior wall, using interlocking stitches (fig. 13) and continuing toward the greater and lesser curvatures.

The stomach is removed by cutting away the anterior wall, where vessels are clamped and ligated (fig. 14). The greater and lesser curvatures and the anterior wall are closed by continuous catgut, using the over and over oblique stitch (fig. 15*A*), which we devised in 1912. This suture only inverts a very small portion of the edge of the jejunum and the gastric wall (fig. 15*C*). A second layer of gastrointestinal catgut is used employing the Cushing stitch (fig. 15*B*). The anterior wall of the anastomosis is completed with a third row of continuous wax silk sutures. The right portion of the split mesocolon is sutured high on the anterior wall of the stomach so that the anastomosis is well below the mesocolon (fig. 16). Figure 17 illustrates the relationships. Figure 18 shows a high gastrectomy in which the mesocolon was short, and could not be brought over the anastomosis to the anterior surface of the stomach. If, in a high resection, the mesocolon is fat, we do not suture the mesocolon too high because of interference with the chest wall. We feel that it is much better to leave it in its normal position, and we have never seen any mechanical difficulty resulting from this. We never suture the split mesocolon to the jejunum, and have had no difficulties with this method. The mesocolon becomes agglutinated within a few hours after the operative procedure. We have never had a herniation through the small mesocolic slit.

CLINICAL END RESULTS

In a follow-up of 1,200 of these patients in both groups, we found that 95% were free of symptoms, had gained from 15 to 50 lb. (6.8 to 22.7 kg.), were on a full diet, and required no medication. A small number complained of fullness after eating, perspiration and weakness, and cardiac palpitation after each meal that lasts from 10 to 30 minutes. These symptoms disappeared after three to six months, and can be ascribed to a reflex of the vagus nerve and its branches. In a number of patients these symptoms disappeared after the stomach began to empty in from 15 to 30 minutes. In the remaining 5% of cases there were symptoms of distress that could not be explained on the basis of a faulty emptying time, or by roentgenological observations. Some of these were diagnosed as spastic colitis, others as visceral neurosis. Such conditions usually occur in highly emotional persons in whom it is difficult to ascertain whether their symptoms have an organic cause.

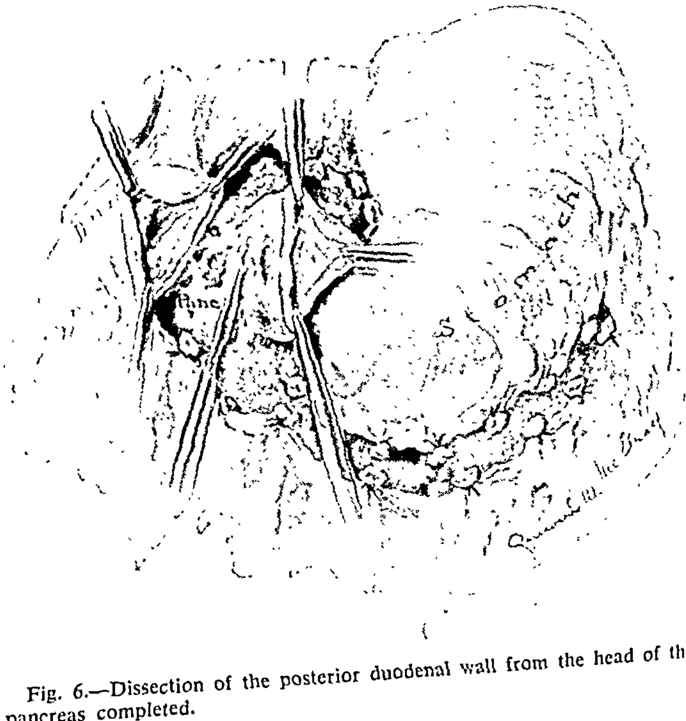

Fig. 6.—Dissection of the posterior duodenal wall from the head of the pancreas completed.

It was also observed that in patients whose stomachs at first emptied slowly, the emptying time after three to six months was between 15 and 30 minutes. This shows that the stomach and jejunum undergo muscular changes as the result of their new mechanical function.

The acidity following subtotal gastrectomy corresponds with that reported by Berg and Lewisohn. At the end of two weeks, 5% of these patients showed a free acid of from 10 to 15 units, with a total acidity of from 25 to 30 units. In the remaining group, there was no free acid, and the total acidity was from 5 to 10 units. Subsequent follow-up revealed no change from the immediate postoperative analyses. We believe that the low acidity among these patients can be attributed to the rapid emptying time of the stomach achieved by a high resection, preventing reflex irritation and the formation of hydrochloric acid. There has been almost no change in the blood picture postoperatively. Both the hemoglobin level and red blood cell count remained the same or increased slightly.

SUMMARY AND CONCLUSIONS

Experience with gastric resection over a period of 33 years in the stomach groups at Michael Reese Hospital, Mount Sinai Hospital, and the Franklin Boulevard Community Hospital have led us to the conclusion that the mortality in 1,796 nonselected cases of gastric, gastrojejunal, and duodenal ulcers justifies subtotal gastrectomy as the operation of choice for the surgical treatment of an ulcer. In group 1, in which there were 950 cases, the mortality was 3.5%, and in group 2, in which there were 846 cases, it was 1.4%.

The technique of a posterior Polya mesocolic resection, with the anastomosis across the entire width of the stomach, has been most satisfactory. That it presents very little mechanical difficulty is shown by the small number of cases in group 1 in which it was necessary to use a Levine tube with Wangensteen suction to aspirate the stomach.

While gastroenterostomy usually produces gastrojejunal ulcers in 20 to 30% of the cases, this complication occurred in less than 1% in our series following high subtotal gastrectomies. Other plastic operations are also unsatisfactory, since there is often a recurrence of the ulcer.

The removal of about 75% of the stomach is one of the important factors in the success of subtotal gastrectomy. The amount of stomach resected does not affect the mortality and morbidity. Subtotal gastrectomy is indicated for patients with a history of a second hemorrhage, a mechanical obstruction of the pylorus or duodenum, or those who have not responded to medical therapy after a sufficient trial. Medical treatment should be instituted in patients with slight symptoms, but those whose symptoms interfere with earning their livelihood should be treated surgically.

In 93 cases in which we did a cholecystectomy in addition to the subtotal gastrectomy, the morbidity or mortality did not rise. We believe in doing a cholecystectomy only if cholelithiasis is present.

The clinical end results in 1,200 cases in which a subsequent follow-up was done revealed that 95% of the patients were well, on a full diet without medication, had a normal blood picture, and showed an increase in weight from 15 to 50 lb. (6.8 to 22.7 kg.). All this should be ample proof that this operation, although a major surgical procedure, justifies itself.

ANTIBIOTICS IN TREATMENT OF PANCREATIC FIBROSIS, WITH EMPHASIS ON TERRAMYCIN

H. Shwachman, M.D., B. K. Silverman, M.D., P. R. Patterson, M.D.
and
L. J. Zheutlin, M.D., Boston

The beneficial effects of aureomycin in the management of patients with pancreatic fibrosis (mucoviscidosis) have been demonstrated.[1] An extension of observations begun three years ago, and including over 100 patients, shows a favorable response in over 90%. Anticipation of the appearance of refractoriness to aureomycin and the poor response of the occasional patient to aureomycin suggested the use of terramycin.[2] The present report is an evaluation of terramycin in the treatment of 49 patients with pancreatic fibrosis. All patients, with two exceptions (the patients in cases 2 and 3), had pulmonary infections of varying severity. A brief note concerning the efficacy of terramycin has been made.[3] A full description of this disease is given elsewhere.[4] The main clinical features drawing attention to this condition in early infancy are hunger, with failure to gain weight on an adequate caloric intake; the passage of large, foul, and frequent stools; chronic cough; and excessive sweating. The index of suspicion should be high when examining siblings of a child with a proved case. Although a variety of laboratory examinations have been described to aid in establishing a diagnosis,[5] the most reliable one is an examination of the duodenal fluid obtained by intubation. The duodenal fluid in a typical patient is scanty and has increased viscosity and absent to markedly reduced pancreatic enzyme activity (trypsin, carboxypeptidase, lipase, and amylase). Observations from this laboratory indicate that all these criteria need not be present in every patient with this disease.

The most incapacitating feature of the disease, and the chief cause of death, is chronic pulmonary infection. The earliest respiratory symptom is usually cough, which often appears during the first few months of life. The cough may become increasingly severe and is associated

with wheezing respirations or dyspnea; or it may become paroxysmal, suggesting pertussis. Repeated attacks of upper respiratory tract infections and bronchopneumonia are common. Progression of the pulmonary process may lead to bronchiectasis, empyema, and lung abscesses. Staphylococci are constantly found in association with the pulmonary infection.

Many patients show evidences of growth retardation and malnutrition. Some have a protruding abdomen and a prominent forehead. Those patients with advanced pulmonary infection are dyspneic and may have a typical cough, an emphysematous chest, clubbing of the fingers, cyanosis, and decreased vital capacity and exercise tolerance. On the other hand, patients with minimal involvement may present no abnormal physical findings. Roentgenograms of the chest in the early stages of the disease show hyperaeration with minimal evidence of infection. As the disease progresses, there is evidence of diffuse, patchy areas of emphysema and atelectasis, with dense hilar shadows.[6] Occasionally the chest roentgenogram may be sufficiently suggestive to give the clinician the first clue as to the presence of this disease.

In the management of these patients emphasis has shifted from the nutritional aspects to attempts at control of the associated pulmonary infection. The nutritional regimen consists of a high caloric, high protein diet with some restriction of fat and a liberal daily allowance of water-miscible multivitamin preparations. In small infants protein hydrolysates are freely prescribed. In addition, pancreatic substitution products [7] are administered to these patients at meal time.

In the control of the pulmonary infection numerous chemotherapeutic and antibiotic agents have been employed, either singly or in combination. Several sulfonamide compounds have been used, with temporary improvement in some patients. Penicillin and streptomycin have been employed both systemically and by aerosol. Administration of these antibiotics by aerosol has proved effective, especially when given for short periods; however, prolonged use is burdensome and often results in a diminished response. The introduction of aureomycin has resulted in a remarkable alleviation of the symptoms of most patients. A beneficial effect has been observed even in those patients with far-advanced bronchiectasis. Unfortunately, relapses of the pulmonary infection occur soon after the complete withdrawal of aureomycin, so that prolonged daily therapy is necessary. Some patients who responded well to aureomycin when it was first employed showed a poor response or no beneficial effect after a prolonged period of therapy. In addition to the control of the pulmonary infection, the treatment of the pulmonary involvement in this disease should be directed toward liquefying the thick, tenacious mucus that seems to be responsible, in part at least, for the associated obstructive phenomena.

The outlook for children afflicted with pancreatic fibrosis has been considered hopeless in the past. This pessimistic attitude is being modified as newer knowledge and greater experience are obtained. The increased clinical awareness of this condition in recent years has resulted in the recognition of many cases at an earlier age than was formerly the case. The prognosis in those patients with minimal pulmonary involvement, or in those in whom the disease is recognized early, should be much better than it was formerly.

PLAN OF STUDY

A total of 49 patients are included in this study, which was started in February, 1950, and continued through May, 1951. In each patient the diagnosis of pancreatic fibrosis was made by examination of the duodenal fluid. In many instances the diagnosis was corroborated by failure to find trypsin in one or more stool specimens,[5c] by failure of the patient to digest gelatin as determined by plasma glycine measurements,[5b] and by the patient's failure to absorb vitamin A when it was fed in an oily base.[5a] These patients were followed either in the hospital or at frequent intervals on an outpatient basis. The patients ranged in age from a few days to 16 10/12 years. They are divided into three groups as shown in table 1.

Group A consists of 13 patients who were treated with terramycin as the sole antibiotic from the time of diagnosis. Group B consists of 16 patients who had been treated with aureomycin as the only antibiotic prior to the administration of terramycin. Group C consists of 20 patients who had been treated with a variety of agents, such as sulfadiazine, aerosol penicillin and streptomycin, and intramuscular penicillin. In addition, aureomycin had been employed in each patient in group C for at least one year. Thus, the first group affords an opportunity for the observation of exclusive terramycin treatment, while the latter two groups permit comparison of the effectiveness of terramycin with other agents in the same patient.

At each clinic visit the history was carefully reviewed with respect to the following factors: respiratory infections, fever, cough, wheezing, exercise tolerance, physica activity, school attendance record, disposition, appetite, dietary habits, frequency and nature of bowel movements, sweating, and details of medication. The patient were weighed, measured, and examined. Laboratory examinations consisted of frequent nose and throat cul

* Age at time of death.

tures, roentgenograms of the chest, and occasional hemoglobin and leukocyte counts. Photographs were taken at frequent intervals. Close contact was maintained with patient's families between clinic visits, and the patients were seen whenever there was any question of the status. Some patients reported at weekly intervals, whereas others came once every two or three months, depending on their condition and other circumstances.

DOSAGE AND MODE OF ADMINISTRATION

The oral dose of terramycin ranged from 7 to 30 mg. per kilogram of body weight per day. Smaller or less severely ill infants received as little as 50 mg. a day in one dose, whereas older or sicker patients received as much as 750 mg. a day in two or three divided doses. Most patients received the total oral daily amount in a single dose. When acute respiratory infections developed with this schedule, the dose was increased to approximately 50 mg. per kilogram per day, given two to four times daily for the duration of the infection. Occasionally during an acute infection, supplementary aerosol penicillin (50,000 Oxford units) and streptomycin (50 mg.) were administered three or four times a day for about one week. Three patients in group A (cases 1, 5, and 9) received this supplementary treatment for brief periods at the time diagnosis was established.

	Nutritional status	6 (33, 37, 40, 45, 46, 47)	6 (30, 31, 36, 39, 43, 49)	4 (32, 38, 44, 48)	4 (34, 35, 41, 42)

* Figures in parentheses are case numbers. See table 1.

Terramycin was used in four forms. The gelatin capsules contained 50, 100, or 250 mg. of terramycin and were given to the older children capable of swallowing capsules. Two cherry-flavored liquid preparations, one with a concentration of 250 mg. per 5 ml. and the other with 100 mg. per 0.5 ml. (as measured by calibrated dropper), were administered to the infants or to children who could not or would not swallow capsules. The concentrated liquid preparation was particularly valuable because of the ease with which it was administered. A preparation designed for aerosol therapy was used in five patients in a 50 mg. dose per treatment for periods up to 10 days. This preparation appeared to be irritating in this concentration.

BACTERIOLOGICAL STUDIES

Nasopharyngeal and oropharyngeal cultures were taken from all patients at the start of terramycin therapy and frequently on subsequent visits. Staphylococcus aureus was isolated from the nasopharynx in all 13 patients in group A at the start of therapy. After terramycin administration, staphylococci were still present in the nasopharynx of the nine patients on whom follow-up cultures were taken, even after 13 months of continuous therapy. No striking change in the pharyngeal flora was encountered in this group.

In the 36 patients of groups B and C, the following micro-organisms were isolated from the nasopharynx at the start of terramycin treatment: staphylococci, 27 cases; Pseudomonas pyocyanea, 6; Proteus, 5; Candida coli, 2; Hemophilus influenzae, 2; and pneumococci, 1. After varying periods of treatment with terramycin the pharyngeal flora was essentially unchanged. The micro-organisms recovered in 32 of these patients were as follows: staphylococci, 23 cases; Ps. pyocyanea, 6; Proteus, 3; C. coli, 0; pneumococci, 1; H. influenzae, 2; and Neisseria catarrhalis, 1.

In some instances the in vitro sensitivity of the micro-organisms isolated was tested against terramycin and other antibiotics. At the beginning of the study a test tube titration method, a modification of that devised by Randall and co-workers [9] for penicillin sensitivity, was used. The results of the observations made on the Staph. aureus obtained at varying periods during the study were as follows: 18 of 23 micro-organisms tested were found to be sensitive to aureomycin; 17 of 22 were found sensitive to terramycin; 9 of 11 were found sensitive to penicillin; and each of 11 was found sensitive to streptomycin. The level of sensitivity is taken as 2 μg in the case of aureomycin and terramycin, 2 Oxford units for penicillin, and 0.5 mg. for streptomycin. It is interesting to note that in some of the patients who showed a very striking clinical improvement the staphylococci isolated from the nasopharynx remained resistant in vitro to terramycin. Later in the study, sensitivity determinations were carried out by a modification of Bondi's method,[10] with paper discs and disc tablets. The results of these studies indicate no consistent correlation between the sensitivity of the staphylococci isolated from these patients and the clinical response.

CLINICAL RESULTS

The clinical effect of terramycin has been evaluated under the following two categories. 1. The effect on the respiratory features, including degree, severity, and frequency of cough, frequency of respiratory infections, fever, wheezing, dyspnea, exercise tolerance, and digital clubbing. The roentgenogram of the chest was also considered in the evaluation. 2. The effect on the nutritional status and general well-being, including changes in

weight, alteration in nature and frequency of bowel movements, appetite, degree of physical activity, disposition, alertness and interest, and number of days absent from school. The over-all response of each patient to terramycin is presented in table 1. Table 2 shows the clinical response to terramycin evaluated in the manner referred to above.

Respiratory Symptoms.—All patients in group A showed pronounced improvement in respiratory symptoms. Improvement in cough was the most striking change and usually occurred within a week after the institution of therapy. This improvement occurred in spite of the fact that some of these patients had severe and prolonged symptoms with presumably irreversible changes. The parents of several of these patients made the comment that their child was free of cough for the first time since birth. Figure 1 demonstrates the improvement in the roentgenogram of the chest of the patient in case 11. This child had been troubled from the age of one month with a cough severe enough to keep him and his family awake many nights. The diagnosis was made when he was three years of age. Within a week after the institution of terramycin therapy he became cough-free and has remained so through the date of this report, a period of four months. Similar responses were noted in the other patients in group A. Changes also occurred in the objective physical findings, such as the disappearance of rales and the improvement in dyspnea and cyanosis when these were present. Digital clubbing became less pronounced in some patients. Acute infections of the respiratory tract occurred infrequently in this group, and the infections were not severe when they did occur. Usually the patient responded quickly when the amount of terramycin administered was increased temporarily.

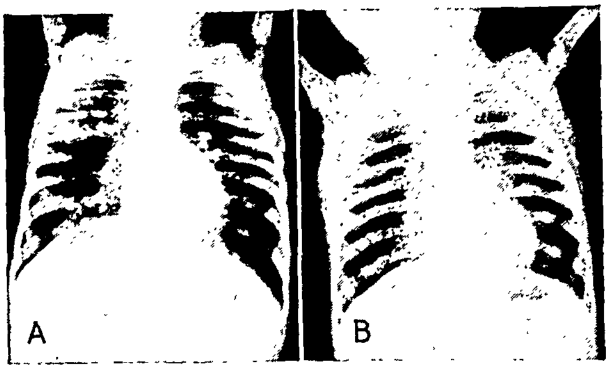

Fig. 1.—Roentgenogram of the chest of patient in case 11, *A*, before being given terramycin and *B*, seven weeks after start of terramycin therapy, 250 mg. daily.

The evaluation of the response of patients in groups B and C was more difficult, because these patients had already received antibiotics for varying periods of time. The patients in group B had previously shown the same dramatic response when first given aureomycin. The patients in these groups were generally older and had more advanced pulmonary disease. For the purpose of the study, terramycin was substituted for aureomycin at the same dosage level. From previous experience it was known that the discontinuance of aureomycin would result in a recurrence of respiratory symptoms; therefore, if a patient who had been relatively free of respiratory symptoms with aureomycin therapy continued to do well or did better with terramycin, the response was considered "good" or "excellent." If a patient was relatively free of respiratory symptoms with aureomycin therapy but showed evidences of relapse with terramycin, the response was considered "poor." Other patients, who were doing only fairly well or poorly with aureomycin therapy, improved somewhat with terramycin and were considered to have had a "fair" or "good" response. Still others in these groups were doing poorly with aureomycin therapy and continued to respond poorly to terramycin therapy.

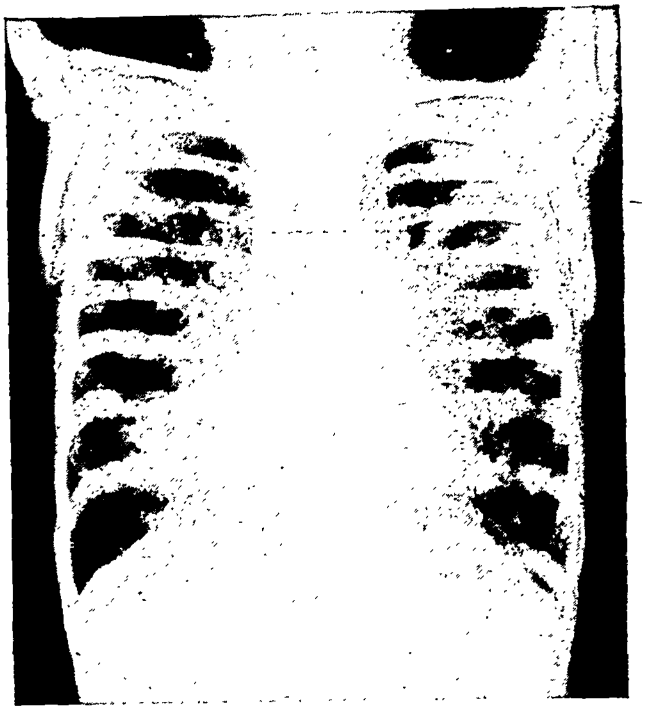

Fig. 2.—Roentgenogram of the chest of patient in case 27 taken one month before death.

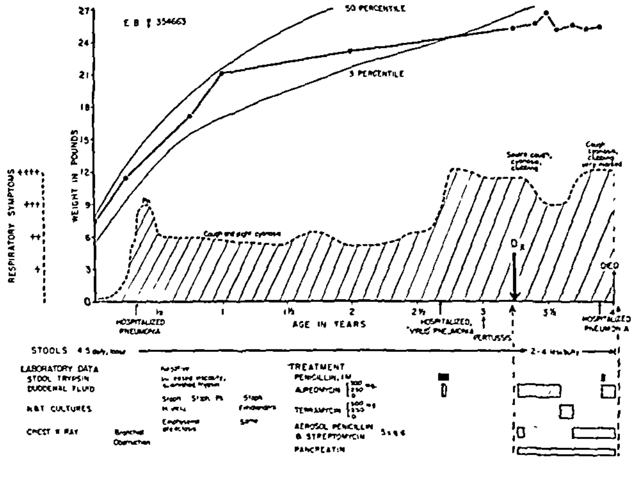

Fig. 3.—Course of patient in case 27. Note failure to respond to treatment. This patient had far-advanced pulmonary disease when a diagnosis was made at the age of 3 5/12 years.

Three patients (cases 27, 38, and 48) who had an initial poor or fair response to terramycin are now dead. The postmortem examination in each case showed far-advanced bronchiectasis, with patchy areas of emphysema and atelectasis. The roentgenogram of the chest of the patient in case 27, taken one month before death, is shown in figure 2. This patient's course is presented in figure 3.

General Well-Being and Nutritional Status.—Improvement in well-being and nutritional status was most marked in the patients in group A. Concomitant with improvement in respiratory symptoms, there was increased physical activity and rapid gain in weight, often accompanied by striking improvement in disposition. The few children who had poor appetite as a result of severe pulmonary infection regained their former excellent appetite. In general, physical development was accelerated in cases in which it had been retarded prior to therapy. The remarkable gains in weight after the institution of terramycin therapy in the patients of group A is shown in table 1. Figures 4 and 5 illustrate the changes observed in the patient in case 5. Patients in groups B and C showed a less dramatic improvement in weight and general well-being than those in group A; however, improvement in the nutritional status took place in the majority of patients (table 1).

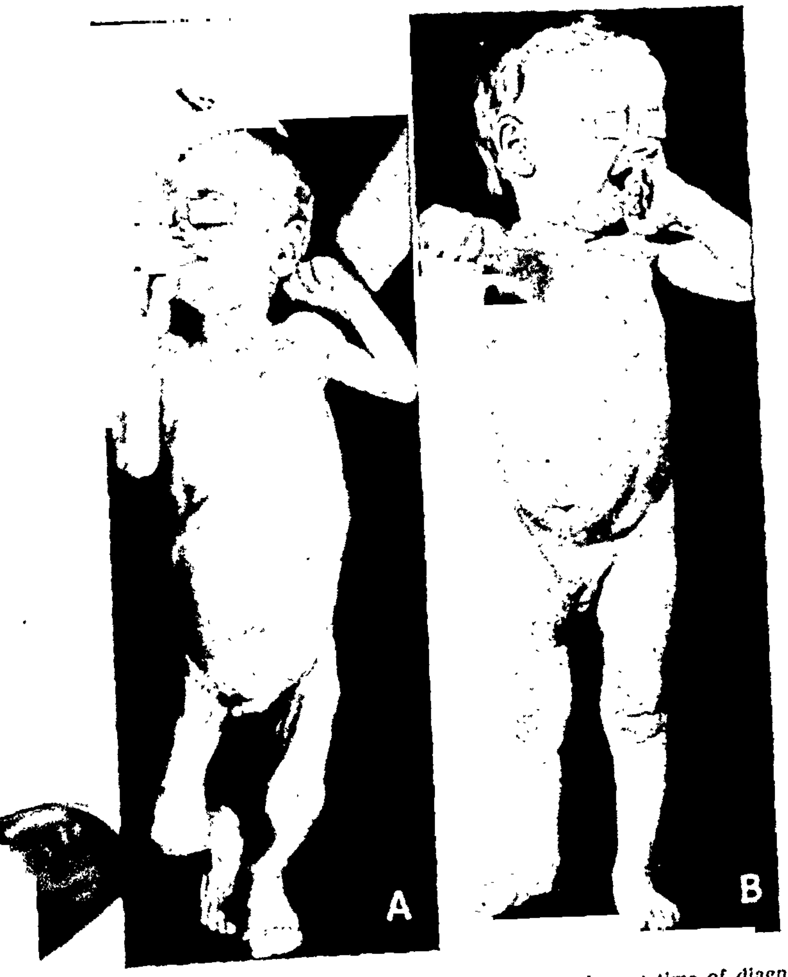

Fig. 4.—Photographs of patient in case 5, *A*, taken at time of diagnosis and *B*, 10 weeks later after treatment with terramycin.

SPECIAL PROBLEMS IN MANAGEMENT

Relapse.—In general, when terramycin therapy was discontinued for brief periods and no other antibiotic was substituted, the recurrence of pulmonary symptoms was noted. With the resumption of terramycin therapy, these symptoms disappeared. This has been our previous experience with aureomycin. It appears, therefore, that prolonged and continuous antibiotic therapy is necessary if respiratory symptoms are to be kept at a minimum.

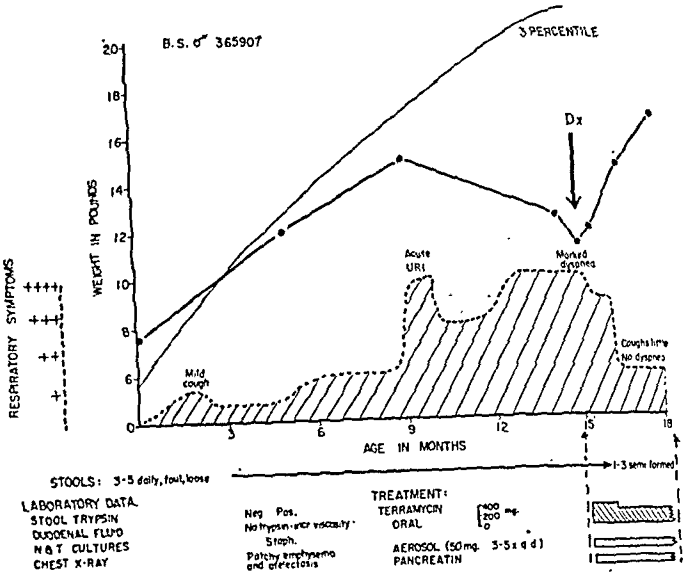

Fig. 5.—Course of patient in case 5. Note rapid gain in weight and improvement in respiratory symptoms after the beginning of terramycin treatment. URI = upper respiratory infection.

Undesirable Reactions.—In the dosage schedule employed, terramycin did not produce any undesirable reaction, except for one patient in whom mild diarrhea developed (case 32). One patient (case 30) who vomited when terramycin was given in capsules tolerated the dru well when it was given in concentrated liquid form. Another patient (case 20) vomited the oral preparations fo a short time and was later able to tolerate the drug an responded to terramycin aerosol.

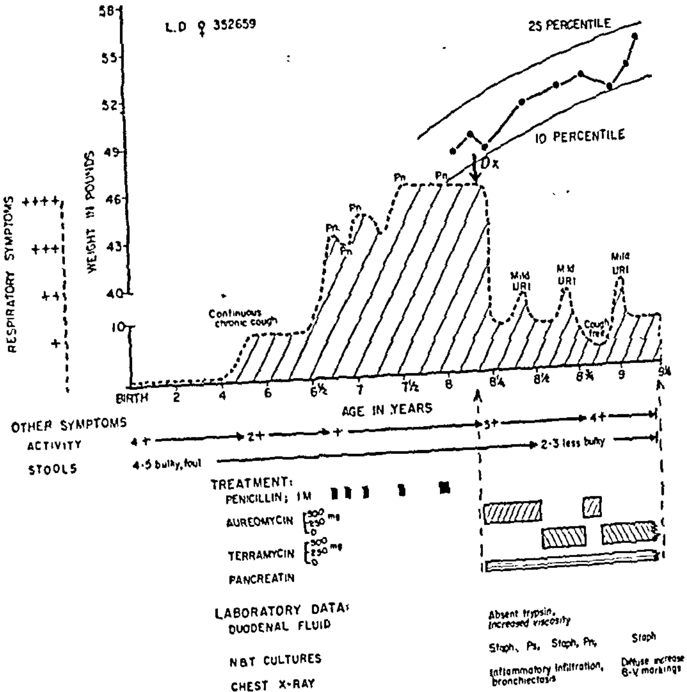

Fig. 6.—Course of patient in case 47. She had a favorable clinica response with both aureomycin and terramycin. Note the late age a which diagnosis was made. This patient had many attacks of pneumoni in the two years prior to referral to this clinic. There was no history o pulmonary symptoms during the first four years of life. Pn = pneumoni URI = upper respiratory injection, and BV = bronchovascular.

Refractoriness.—A diminishing clinical response to terramycin with prolonged therapy has not yet become a problem. Those persons whose initial response was good or excellent continue to do well. Judging by our experience with aureomycin, we anticipate some degree of refractoriness after prolonged therapy. Two patients (cases 38 and 48) had an initial favorable response to aureomycin but failed to respond after prolonged treatment. When the therapy was changed to terramycin, one patient (case 38) showed no improvement while the other patient (case 48) showed some temporary improvement. Both patients have died.

COMPARISON OF RESULTS WITH TERRAMYCIN AND AUREOMYCIN

Table 3 compares the clinical response of the 36 patients in groups B and C. Twenty-two responded equally well to both drugs; seven had a somewhat better response to terramycin and seven to aureomycin. Thus it would appear that the two drugs are equally efficacious in the management of pancreatic fibrosis. Figure 6 presents more detailed data on a patient who had a good response to both drugs.

COMMENT

The improvement that may follow antibiotic therapy can be so striking that the clinical appearance of the patient may cause one to question the validity of the original diagnosis. In spite of this clinical response, repeat duodenal fluid studies will reveal the characteristic findings that originally led to the diagnosis. Indeed, the withdrawal of therapy usually brings on a recurrence of former respiratory symptoms. We should like to emphasize the importance of establishing a diagnosis early so that therapy can be started before extensive pulmonary lesions become well established. The failure of therapy in a patient with extensive pulmonary involvement, as in the patient in case 27, is understandable and in contrast to the excellent response in the patient in case 4, whose treatment was begun at 3½ months of age. Another reason for starting therapy early is the observation that infants may have more trouble with thickened bronchial secretions and are more likely to die from the disease than older children. In the group of patients discussed, the diagnosis was established when they were under 3 months of age in 11 instances, under 9 months in 18 cases, and under 2 years in 36 cases (73.5%). The onset of pulmonary symptoms was noted in 26 patients before the age of 3 months, in 14 patients between 3 and 9 months, and in 7 patients over the age of 9 months. Two patients show no pulmonary symptoms at the time of this report.

Although great strides have been made in the early recognition of this disease, we must attempt to shorten further the span between the appearance of symptoms suggesting this condition and the date of establishing a diagnosis and instituting therapy. In this study approximately 54% of the patients had pulmonary involvement as demonstrated clinically and/or by roentgenogram by the age of 3 months; however, in only 22% was the diagnosis made by this age. It appears that the age at the time of diagnosis and establishment of a sound therapeutic regimen may be one of the deciding factors in the outcome. The severity of the disease is equally important, however, and this is oftener reflected by the intensity of the pulmonary symptoms than by the degree of gastrointestinal dysfunction. It is too early to draw conclusions as to the eventual outcome of these patients; nevertheless, comparison with the best results obtained prior to three years ago would be most favorable. The only major change in our therapeutic program has been the introduction of the newer antibiotics. The formerly used agents, such as sulfadiazine, penicillin, and streptomycin, were effective and often produced favorable results. The combined use of penicillin and streptomycin in aerosol form, 50,000 units of the former plus 50 mg. of streptomycin from two to five times daily, is still useful in the most refractory cases. In these same persons the use of a combination of agents may be most effective, such as combinations of penicillin and streptomycin in aerosol form, orally administered terramycin, or aureomycin plus sulfadiazine. Our experience with chloramphenicol (chloromycetin®) is limited, and it has been thought useful in the most advanced cases when combined with other drugs. The use of chloramphenicol alone in some early cases did not seem to be as satisfactory as either aureomycin or terramycin. Further experience is necessary for proper evaluation of this drug. We have been impressed with the effectiveness of sulfadiazine after prolonged periods of aureomycin or terramycin therapy. In the past we had been limited in the number of effective agents, but today, with so many, the rotation from one effective drug to another may become the ideal form of therapy.

The emergence of resistant strains of staphylococci in the respiratory tract and the appearance of a new flora with resistant micro-organisms were problems of great concern when this study was started. Ps. pyocyanea was recovered with greater frequency in those patients treated with a variety of antibiotics over prolonged periods of time; however, in those patients treated with terramycin alone and for relatively shorter periods the bacterial flora of the nasopharynx showed little change. We were alert for the occurrence of moniliasis, but this complication did not occur except in a few patients terminally. The emergence of terramycin resistant staphylococci in vitro did not correlate with the therapeutic response. In spite of the presence of resistant staphylococci in the nasopharynx, patients continued to show a favorable clinical effect. This suggests that terramycin may have an action other than a pure antibacterial one. A similar action was suspected in the case of aureomycin. In studying the action of aureomycin in patients with pancreatic fibrosis, Stowens [1b] points out from his nitrogen balance studies an almost fourteenfold increase in the amount of nitrogen retained. He attributes this to three factors: (1) an increase in the amount of nitrogen voluntarily ingested, (2) an increase in the amount of nitrogen absorbed, and (3) an increase in utilization of absorbed nitrogen. An action similar to this in the case of terramycin has not been demonstrated but would appear likely. The weight gains recorded in table 1 of patients receiving terramycin as the sole antibiotic are very striking. This is especially true when one notes that in many instances there was insignificant or no weight gain for weeks before the institution of therapy. The gains recorded are in the same range of magnitude or slightly higher than those reported by Stowens, who used aureomycin. Whether this is due to differences in diet or to the use of pancreatin in most of our patients is difficult to say. We felt that the administration of pancreatin was advisable in view of its effect in improving nitrogen absorption. Pancreatin per se has no ameliorative effect on the respiratory tract symptoms. A few patients were treated without pancreatin for varying periods of time, and it was felt that this product did not interfere with our appraisal of antibiotic therapy. The changes in the intestinal bacterial flora have not been studied by us. Terramycin alone does not improve the defective proteolytic action in the small intestine, as determined by oral gelatin feedings and by comparison of the plasma glycine nitrogen of a two hour postprandial specimen with a fasting specimen. In this regard terramycin does not behave like pancreatin. It should also be noted that failure to absorb vitamin A in an oily base persists with this antibiotic therapy.

Although emphasis in this presentation is given to the antibiotic agent, other aspects of management must not be neglected. Our dietary regimen includes a high caloric iet with a high protein and slightly reduced fat intake, nd a high water-miscible, multivitamin intake plus the addition of pancreatin. The use of such agents as iodides, antihistamines, and bile salts may have a place in selected circumstances; however, since these measures alone do not produce striking improvement in most patients with pulmonary involvement, the greatest part of the favorable response must be attributed to the daily use of the antibiotic.

The inclusion of two patients (cases 17 and 30) who had meconium ileus at birth should be noted. In these infants, the clinical and laboratory features of pancreatic fibrosis have developed and have responded to therapy. Great credit is due the surgeons who have been able to relieve the meconium obstruction by surgical measures in the first few days of life in over 50% of the patients with this condition in the past three years.

SUMMARY AND CONCLUSIONS

1. An evaluation of terramycin in the management of 49 patients with pancreatic fibrosis is presented. Thirteen patients (group A) received no previous antibiotic therapy. The remaining 36 (groups B and C) had received aureomycin and other antibiotic and chemotherapeutic agents for varying lengths of time.

2. Each of the 13 patients in group A had an excellent response as judged by the improvement in pulmonary symptoms, well-being, and nutritional status. Of the other 36 patients in groups B and C, all but 5 responded favorably. No serious untoward reaction to terramycin was encountered. Clinical relapse usually occurred when the antibiotic was discontinued.

3. The effectiveness of terramycin is compared with that of aureomycin in the management of pancreatic fibrosis in 36 patients. It is concluded that the two drugs are equally efficacious. In seven patients aureomycin seemed to be more effective than terramycin, and in seven patients terramycin seemed more effective than aureomycin. In the remaining 22 patients both drugs were alike in their effect.

4. Terramycin is effective in the management of pancreatic fibrosis when administered in small doses of from 7 to 30 mg. per kilogram of body weight on a daily basis. Early diagnosis and prolonged therapy results in the most favorable clinical response. Suggestions for the management of refractory cases are made by the use of combinations of antibiotics and the rotation of these agents.

5. The importance of other measures that have been mentioned in the management of patients with this disease should not be neglected. Indiscriminate use of antibiotics without proper control and frequent observations should be discouraged. The employment of adjunct measures, such as dietary control, good nursing care, personal hygiene, and the use of expectorants, should be part of the provision of complete medical care for each patient.

Perforated Peptic Ulcer.—In evaluating the methods of therapy for a complex clinical problem, such as an acute perforated peptic ulcer, the important consideration is not whether one therapy should be employed to the exclusion of another but rather wherein each may conceivably be used with the greatest advantage. . . . At present, we are disposed to favor surgical exploration and the use of simple suture in all early acute perforations, whether the diagnosis is suspected or definitively proved, unless the condition of the patient contraindicates a laparotomy or the use of an anesthetic. Likewise, if a case is seen after a lapse of 12 to 24 hours without convincing clinical signs of localization, we still prefer this approach providing no operative contraindication exists. If the clinical evidence in such delayed cases indicates a definite spontaneous containment of the effects of perforation, we are prepared to entertain the use of the nonoperative method. Our decision, to a large degree, would be determined by the condition of the patient. Finally, we are prepared to modify our preference for the use of simple suture in acute perforations which occur within or adjacent to chronic calloused penetrating ulcer, particularly at the site of the reentrant angle of the stomach. In such cases, in which closure may prove difficult or uncertain, a partial gastrectomy may be justifiable providing the condition of the patient is favorable and the experience of the surgeon is adequate.—Sigmund Mage M.D., and Benjamin A. Payson, M.D., A Consideration of th Present Status of Simple Suture in the Treatment of Acut Perforated Gastroduodenal Ulceration, *Surgery, Gynecology an Obstetrics*, May, 1952.

ELECTROCARDIOGRAPHIC PATTERNS IN PATIENTS WITH SECOND MYOCARDIAL INFARCTIONS

STUDIES OF TWELVE PATIENTS WITH ANTERIOR MYOCARDIAL INFARCTION FOLLOWED BY POSTERIOR MYOCARDIAL INFARCTION

John A. Mart, M.D., Hugh A. Flack, M.D.
and
Chauncey C. Maher, M.D., Chicago

The electrocardiographic patterns of acute myocardial infarctions are a matter of common knowledge, and the serial changes have been documented by a number of authors. Less attention, however, has been directed to the serial changes due to second infarctions, which are the subject of this study. This report is limited to cases in which an original infarction of the anterior type is followed at a later date by a second of the posterior type.

REVIEW OF THE LITERATURE

On this subject, the earliest pertinent reference we were able to find was that of Levine and Brown [1] in 1929. They reported a series of 46 cases of coronary thrombosis; 6 of these showed both "old and recent lesions." Of these six, one (case 19) showed an electrocardiographic pattern of the anterior type in 1922 and a posterior type pattern five months later.

Four years later, Wood, Bellet, McMillan, and Wolferth [2] said: "Electrocardiographic characteristics of an acute infarct may be altered by changes in the QRS complex caused by previous infarction. . . . Of 36 cases of acute coronary thromboses reported three had electrocardiographic evidences of previous infarction." A second report by Wolferth and Wood,[3] in 1935, stated that the patient "may have had a previous cardiac infarct. However, in our experience this has not prevented the localization of the recent lesion."

Barnes,[4] in 1935, wrote as follows:

> The presence of multiple infarction confuses the analysis of the resulting electrocardiographic changes, and in the final interpretation of such cases all possible infarcts must be sought for and their age sequence determined, if possible, by microscopic study. . . . The presence of a large healed infarct of the anterior portion of the heart may lead the examiner to overlook less obvious, but more recent infarct in the posterior base of the left ventricle; this happened in a case recently reported and led to the serious question of the hypothesis of localization. Moreover, it must be borne in mind that the more recent infarct dominates the RST changes in the electrocardiogram.

Sixteen cases in which an old and a recent infarction occurred as proved by autopsy were reported by Sprague and Orgain.[5] In this group with an old and a fresh coronary occlusion, the occurrence of low voltage and "intraventricular conduction defects" became more prominent in 11 cases, and the "T wave changes characteristic of coronary occlusion" were seen in 9 of the 16 cases.

In a discussion of the value of lead IVF in cardiac infarctions, Burton,[6] in 1945, stated:

> In each of eleven cases in this group electrocardiographic changes gave adequate evidence of two or more separate clinical episodes diagnosed cardiac infarction. It is interesting to note that in two of five cases with evidence of an old anterior infarct upon which had been superimposed a recent posterior infarct the well-marked initial negative deflection of QRS_1 that developed as the result of the anterior infarction, completely disappeared leaving a normal R_1 with the advent of the posterior infarct.

Levy and Hyman [7] recently wrote: "Serial studies of patients with multiple episodes of myocardial infarction will usually enable one to localize the lesion accurately, despite the fact that the final electrocardiogram may show QRS changes of the predominant area of infarction only."

From a textbook standpoint, Graybiel and White [8] (1946) report a case of acute posterior myocardial infarction on an old anterior myocardial infarction. Two electrocardiograms are presented. The authors stated:

> These electrocardiograms show very well, the effect on the record of the superimposition of a fresh posterior myocardial infarct on 2½ year old anterior myocardial infarct, rendering the electrocardiogram more normal in appearance because of the elevation of the T waves in Lead I and in the precordial leads even though the heart is actually more damaged than before, there being now two infarcts instead of one.

Katz [9] said:

> The occurrence of a second acute myocardial infarction is shown in the electrocardiogram by the appearance of the S-T stages. If the new infarct is in the area previously damaged, the record may resemble the type already established, otherwise an opposite or composite form will develop.

White [10] mentioned the subject in his book and specifically said:

> It is of especial interest that evidence of previous myocardial infarction in the limb leads may be more or less neutralized by a new infarct and that the electrocardiogram may actually look

better when a fresh posterior infarct changes an inverted T wave to an upright position in Lead 1, the result of an old infarct; the precordial leads are more discriminating.

With regard to this problem, Friedberg[11] stated: "The electrocardiographic changes produced by the fresh infarct may be neutralized by those of previous infarcts."

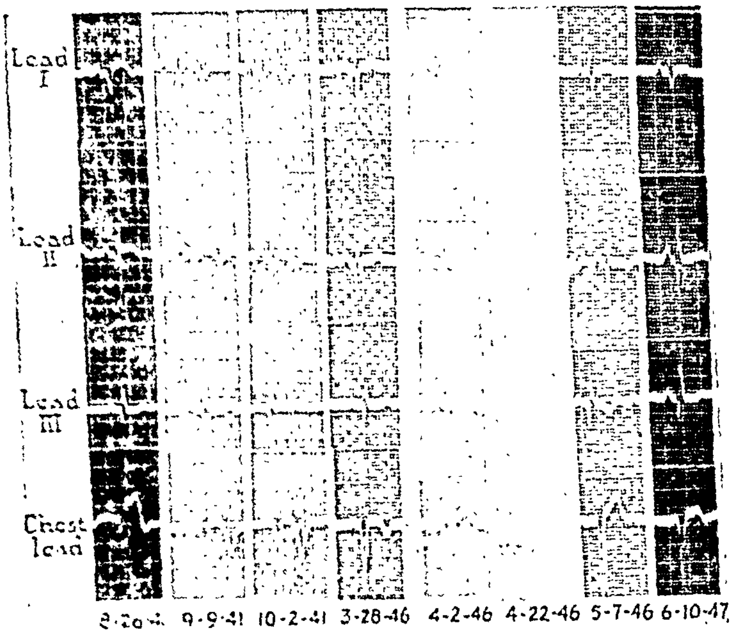

Fig. 1 (case 1).—This series of electrocardiograms was chosen to illustrate the major changes that occurred during the first (anterior) infarction (Aug. 26 to Oct. 2, 1941), the stabilized pattern following this infarction (March 28, 1946), the major changes of the second (posterior) infarction (April 2 to May 7, 1946), and the electrocardiogram revealing residues of both infarctions (June 10, 1947).

He further stated, in regard to "combined anterior and posterior infarction," that "When there is an old infarct on one surface and a fresh infarct on the other the changes due to the recent infarct may be added to or replace hose of previous infarctions."

Bellet and McMillan,[12] in discussing "variations of the usual patterns in posterior infarctions," stated: "Where there has been a previous old anterior infarction acute infarction of the posterior wall is characterized by the typical changes enumerated above." (They described patterns in Q and T waves in leads 2 and 3.) "In addition, T_1 may be inverted and there is frequently an absence of the initial upward deflection with some depression of the R-S-T segment, these additional findings being a result of an old anterior infarct."

MATERIAL AND METHOD

For this study the records of 12 patients with two myocardial infarctions were selected; these patients had an anterior infarction followed by a posterior infarction. The standards for diagnosis were those listed in the "Nomenclature and Criteria for Diagnosis of Diseases of the Heart."[13] The points of diagnosis were protracted precordial pain, variable degree of collapse, fall in blood pressure, mild elevation of temperature, leukocytosis, elevation of sedimentation rate, and the conventional serial electrocardiographic changes.

The charts selected were those in which there were a substantial number of electrocardiograms available for study, with autopsy records in some.

A characteristic single record reads as follows:

G. A. (case 1 in the accompanying table) was born in 1896. His parents lived beyond their 75th year. A brother died of pneumonia; another brother and two sisters outlived him. He had the usual diseases of childhood. At the age of 43, while working as an executive in a packing plant, he was found to have mild hypertension (150/90). At the age of 45 (Aug. 25, 1941), after his evening meal he experienced a bout of severe anterior chest pain, referred into the neck and left arm and lasting 15 minutes. He continued to have pain of similar character throughout the night, with episodes of increased severity. He perspired profusely and was apprehensive.

The following day, he was admitted to Passavant Memorial Hospital, where he remained for six weeks. His temperature for the first eight days ranged from 36.7 to 38.9 C (98 to 101 F). His pulse rate varied from 80 to 120 beats per minute, and his blood pressure varied between 98/64 and 138/80 mm. of mercury. The white blood cell count ranged from 14,000 to 6,500 per cubic millimeter. The Kahn reaction was negative, and the urine was normal. The electrocardiograms taken during this hospital stay showed the conventional changes of an acute myocardial infarction of the anterior type. He returned to work Dec. 1, after a disability of three and one-half months. Between the ages of 46 and 49 (1942 to 1945), his course was uneventful. His blood pressure varied from 120/86 to 140/90.

In his 50th year, on March 28, 1946, after a month's vacation in Cuba, he had recurrent attacks of chest pain and fatigue. An electrocardiogram on April 2 showed distinct changes, and he was again hospitalized at the Passavant Memorial Hospital, where he remained for six weeks. During this stay, his temperature ranged between 36.2 C and 37.4 C (97.2 and 99.3 F). His pulse rate ranged between 70 and 110 beats per minute, and his blood pressure varied between 118/70 and 170/100 mm. of mercury.

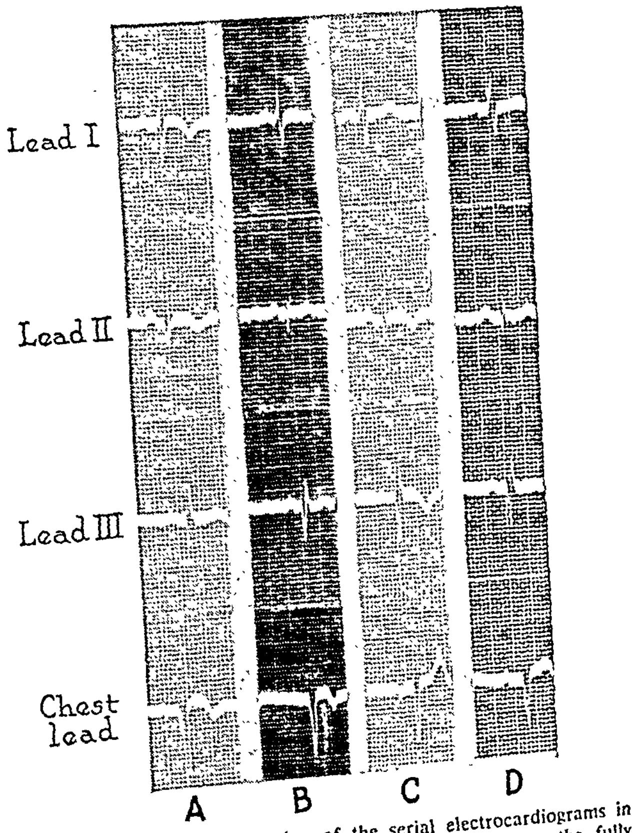

Fig. 2.—This shows a condensation of the serial electrocardiograms in case 9 (see the accompanying table). These tracings illustrate the fully developed anterior pattern (*A*), the residual anterior pattern (*B*), the fully developed posterior pattern that obliterates the residues of the original (anterior) infarction (*C*), and, finally, the residuals of both infarctions (*D*). This typifies the major sequential electrocardiographic changes that are found to occur in our study.

The white blood cell count ranged between 8,900 and 6,900 Again the Kahn reaction was negative and the urine normal The sedimentation of the red blood cells ranged between 30 an

15 mm. in one hour (Wintrobe). Electrocardiograms taken during this episode showed the T wave changes of a posterior wall myocardial infarction.

The patient returned to work in August, 1946. When he was 51 (1947), an allergic dermatitis of the hands developed. In July, 1949, at the age of 53, an unexplained temperature rise occurred and he was hospitalized at the Madison General Hospital. Gradually evidence of cardiac insufficiency with edema developed. Extensive roentgenologic and laboratory studies failed to clarify the cause of his febrile illness. Aureomycin and penicillin therapy had no effect, and sulfadiazine was given with seemingly favorable results. The edema was treated with digitalis and mercurial diuretics, with only fair success.

On Sept. 8, the patient died suddenly, and autopsy was performed by Dr. P. L. Gausewitz.[14] The heart, which weighed 500 gm. and had essentially normal valves, showed occlusion of the left descending coronary artery by an old thrombus. Distad to this point and mediad to the apex of the left ventricle, there was a cardiac aneurysm, 7 by 6 cm., with calcification of the pericardium over this area (the first infarction).

The clinical and laboratory records of the other 11 patients were as comprehensive as the case history presented above. Certain variations appeared, such as the time interval between the first and second infarctions. The minimal time was six weeks and the maximum six years. The clinical course of each patient was modified to some extent by coexisting diseases such as hypertension, peptic ulcer, cholelithiasis, trauma, and a variety of infections. Tabulation of pertinent details of the records in 12 cases of anterior infarction followed by posterior infarction is presented in the accompanying table.

The electrocardiographic records routinely consisted of the three standard limb leads. Tracings from 1937 to 1946 included also a single chest lead, usually CF_4. From 1946 to 1951, the chest leads were routinely CF_2, CF_4, and CF_5, or V_2, V_4, and V_5.

Data in Twelve Cases of Anterior Infarction Followed by Posterior Infarction

Case No.	Age at Time of Infarction, Yr.		Approximate Time Interval Between Infarctions	Other Diseases	Status of Patient at Time of Report	Postmortem Observations (Heart)
	Anterior	Posterior				
1	45	50	4½ yr.	Allergic dermatitis; fever of unknown origin	Dead (third infarction)	Old anterior infarction with cardiac aneurysm; old and recent posterior infarction
2	45	51	6 yr.	Fracture of elbow and femur	Dead (second infarction)	Old anterior infarction involving septum; recent posterior infarction with myocardial rupture; recanalized thrombus right coronary artery
3	54	57	3 yr.	Hypertension; arthritis	Living	....
4	37	38	1 yr.	Alcoholism	Dead (chronic cardiac insufficiency)	Autopsy not made
5	51	54	3 yr.	Hypertension; hemorrhoids; prostatism	Dead (third infarction)	Autopsy not made
6	56	56	6 wk.	Thrombophlebitis	Dead (second infarction)	Autopsy not made
7	57	61	4 yr.	Duodenal ulcer; diverticula of colon; Neisseria gonorrhoeae infection; hypertension	Dead (third infarction)	Autopsy not made
8	47	48	1 yr.	Alcoholism; gallstones; iritis	Dead (third infarction)	Old anterior infarction; old posterior infarction; recent anterior infarction
9	52	54	2 yr.	Psoriasis; obesity; arthritis; hypertension	Living	....
10	57	57	6 mo.	Hypertension	Living	....
11	47	52	5 yr.	Duodenal ulcer; pneumonitis	Dead (cardiac insufficiency)	Autopsy not made
12	57	58	1 yr.	Duodenal ulcer; gallstones; hypertension	Living	....

The left circumflex coronary artery was markedly arteriosclerotic, with hyalinization of the wall and containing a hyalinized calcified thrombus that had been recanalized. There was extensive connective tissue replacement of the myocardium in this area. The right circumflex artery was almost completely occluded at 7 cm. from its origin by what appeared to be old atheromatous lesions (the second infarction).

In the region of the recanalized calcified thrombus, there was a hemorrhage into the wall of the vessel, which had "apparently forced the thrombus out so that it almost occluded the lumen." In this area, there was an acute pericarditis with infiltration of polymorphonuclear leukocytes with acute degenerative changes of the myocardial fibers (the third infarction).

In summary, this case record (substantiated by autopsy) presents the clinical, laboratory, and serial electrocardiographic evidence (fig. 1) of consecutive myocardial infarctions—an anterior followed by a posterior infarction and then, as might be expected, the third infarction, which caused death.

Three of the 12 patients had had electrocardiograms taken prior to the first infarction. The majority of the patients had a few tracings during the first 10 days after the acute episode, and at 7 to 10 day intervals while in the hospital. Between the first and second infarctions, tracings were made at intervals, from one to four per year. During the posterior infarction, the schedule followed was similar to that used during the first infarction. Those who survived had tracings made at variable intervals.

RESULTS

Review of the electrocardiographic records concerned with the primary anterior infarction showed the conventional serial defects. The T waves of lead 1 were typically inverted. There were less definitive changes in

---

[14] Personal communication to the authors.

lead 2. Inversion of the T waves occurred in one or more of the precordial leads. There were elevations of the RS-T segments recorded in 6 of the cases, and coving was evident in 11. In 10 of the group, a demonstrable Q wave was present in lead 1, lead 2, or a precordial lead.

A residual pattern of the first infarction was usually established in the interval of weeks, months, or years between the original, anterior, infarction and the second, posterior, infarction. The T wave in lead 1 remained inverted in five cases, blunt or isoelectric in three cases, and definitely upright in four cases. In the precordial leads, the T wave remained persistently inverted in one or more leads in seven cases. There were slight elevations in the RS-T segments in 7 of the 12 records in the limb and/or the precordial leads. The Q waves of the limb leads or the precordial leads noted during the acute stage did not change significantly in the residual patterns.

With the advent of the second infarction (posterior), conventional serial changes were evident. Most obvious and consistent was the inversion of the T wave in lead 3 in all cases. In the eight cases in which there were residual T wave defects in lead 1, the T wave became definitely upright within from one to four days. Coincident with the inversion of the T wave in lead 3 and the rise of the T wave in lead 1, the T waves of the precordial leads assumed an upright position. In five cases there was definite elevation of the RS-T segments in lead 3, and in three cases some elevation of these segments in lead 2. In two cases the RS-T segment in lead 1 showed some depression, and in no case was there a depression of this segment in any precordial lead. Contrary to expectation, in nine cases there was a slight elevation of the RS-T segments in a precordial lead. In no record was there any significant Q wave alteration that existed as a residual of the old anterior infarction.

Six patients survived for at least one year after the second infarction. Three of these had electrocardiographic patterns apparently the result of both infarctions, two had patterns of the posterior infarction only, and one had an essentially normal pattern.

COMMENT

The primary problem of this study is concerned with the diagnosis of a posterior myocardial infarction following an anterior myocardial infarction. There is a possibility that we have missed documenting an infarction before or during the time the patient was under observation. We believe, however, that our clinical records are accurate, and in three cases (see accompanying table) pathological verification was secured.

Electrocardiographically it is evident from our data that a posterior myocardial infarction superimposed on an old anterior myocardial infarction results in expected pattern changes. Old anterior residual defects, particularly T wave inversions in lead 1 and/or precordial leads, show substantial and prompt obliteration (fig. 2). Q waves in limb or precordial leads, however, were not significantly altered. In some patients the residual of the old anterior infarction reappeared after a few months, and in some the newer posterior pattern predominated. In one record, after 14 months, neither old nor recent infarction was evident.

In previous reports, Barnes,[4] in 1935, appears to have been the first to appreciate clearly, in any given patient presenting symptoms and electrocardiographic evidence of myocardial infarction, the importance of a previous infarct. He also recognized that the primary infarction "confuses the analysis" of the resulting electrocardiographic changes of the second infarct and that the more recent infarct "dominates the RS-T changes."

Other authors appear to have had a more casual interest in the second infarction. Of those who mention the subject, in discussions of the electrocardiographic diagnosis of myocardial infarction, Wood and co-workers,[2] Sprague and Orgain,[5] and Levy and Hyman [7] were interested in the QRS changes, and Katz,[9] in the S-T segments. Sprague and Orgain,[5] Graybiel and co-workers,[8] Friedberg,[11] and Bellet and McMillan [12] spoke of the T wave changes. We would be inclined to emphasize the entirety of the QRS-T pattern changes and the progression of the changes in serial tracings. As the second infarct is reflected in the electrocardiographic picture, the defects of the old infarct are substantially obliterated.

The statement of White [10] that the "electrocardiogram may actually look better when a fresh posterior infarct changes an inverted T wave to an upright position in Lead I" must be qualified. Serially, as the T wave in lead 1 becomes upright, the T waves in lead 3 and possibl in lead 2 are inverting (also Q waves in leads 2 and may appear), all of which are significantly abnormal.

The reappearance of the R wave in lead IVF in tw cases with the advent of the posterior occlusion, as reported by Burton,[6] was not evident in our chest leads.

Completion of this electrocardiographic study of the simple combination of an anterior infarction followed by a posterior infarction indicates that further work is necessary. It would be desirable to review a greater number of case records, substantiated by postmortem findings, to corroborate or modify our conclusions. We hope to present further information at our command, dealing with other combinations of two myocardial infarctions: the converse of the present one, a posterior followed by an anterior infarction; or two sequential anteriors; or two sequential posteriors; or others. The ultimate step, obviously, is the sequence of three or more myocardial infarctions.

CONCLUSIONS

1. The clinical and electrocardiographic records of 12 patients who had sustained two myocardial infarctions —first an anterior type, followed later by a posterior type —were studied with reference to the electrocardiographic changes resulting from the second infarction.

2. A second infarction (posterior) engrafted on a firs infarction (anterior) presents typical electrocardiographic changes in the serial tracings, similar to thos conventionally recorded.

3. The residual electrocardiographic pattern of th anterior infarction is substantially obliterated from t electrocardiographic records by the acute changes of t posterior infarction.

4. Months or years after the second infarction, the electrocardiographic pattern may be that of the posterior (second) infarction, a mixture of defects that are the residual of both infarctions, or a nearly normal pattern.

MEASUREMENT OF BODY WATER

TECHNIQUES AND PRACTICAL IMPLICATIONS

James D. Hardy, M.D., Memphis
and
David L. Drabkin, M.D., Philadelphia

A satisfactory method for the measurement of total body water in the living subject has long been sought. This is not surprising when one pauses to consider the overwhelming importance of water in the body economy. Water furnishes the preponderant single molecular element in the fabrication of tissue. Its presence is essential to the great mass of chemical reactions on which life depends. It furnishes the means of transport of virtually all enzymes, substrates, metabolites, gases, electrolytes, antibodies, and other substances that must be moved to and from the cell. Cellular function itself is affected by abnormal fluctuations in water content.

The methods that have been employed for the measurement of total body water may be considered under three general headings: desiccation procedures, body specific gravity measurements, and dilution techniques.

DESICCATION

The first estimates of body water content were accomplished with desiccation procedures. One of the early studies in man was reported by Bischoff[1] in 1863. He obtained a value equal to 58.5% of the body weight of the cadaver. More recently, Mitchell and his associates[2] have reported a value of 67.85% in a patient who died in congestive heart failure, and Iob and Swanson[3] have recorded a value of 75% in a stillborn infant. However, valuable as are the data obtained by this method, it is obviously not one that can be employed clinically.

BODY SPECIFIC GRAVITY

In 1941 Behnke[4] reported his studies dealing with specific gravity measurements in young men. He showed that in normal subjects the determination of body specific gravity enabled one to estimate the body fat content. Fat, with its low specific gravity of 0.92, was identified as the primary variable that determined body density. From these findings Behnke formulated his now widely accepted concept of the lean body mass. He conceived of the body as consisting of a fat-free portion of essentially constant gross composition and of a variable quantity of fat. He was not at that time primarily interested in determining values for total body water in his subjects, but he might easily have done so, for body water and body fat bear a reciprocal relationship to each other[5]; that is, the less the fat content, the greater is the percentage of water contained in the body. The specific gravity method of estimating body fat content (and body water) has since been amply confirmed.[6]

DILUTION METHODS

A number of substances have been employed in the search for an ideal material, which when introduced into the body would allow the safe and accurate measurement of total body water. Such a substance should not be toxic to the organism. It should equilibrate rapidly with body water. It should not be selectively stored or excreted, and it should not be metabolized. Its concentration in urine or plasma should lend itself to ready measurement. Among the substances that have been used for this purpose are potassium,[7] thiourea,[8] sulfanilamide,[9] tritium (the radioactive isotope of hydrogen, mass 3),[10] antipyrine,[11] and deuterium oxide (heavy water).[12] For various reasons, the first three of these substances are unsatisfactory. Values for body water obtained with tritium agree well with those obtained with specific gravity measurements,[10] but the long half-life of this radioisotope renders its use in human beings potentially hazardous. In addition, its triple mass raises the question of whether its kinetics of distribution are identical with those of ordinary hydrogen, especially since there is evidence that even deuterium (mass 2) behaves differently in high concentrations.[13] Antipyrine and deuterium oxide are currently regarded with a considerable degree of confidence, and they will be considered in some detail.

Antipyrine was first introduced for this purpose by Soberman and his associates in 1949.[14] These observers demonstrated that after injection it was distributed uniformly throughout the body water and that its concentration in body fluids could be determined accurately with the spectrophotometer. They also showed that the values for body water obtained with antipyrine agree closely with those obtained with deuterium oxide (heavy water). Messinger and Steele,[15] and Osserman and coworkers[6b] compared values for body water obtained with the use of antipyrine with those obtained from specific gravity measurements in the same subjects and found a satisfactory correlation between the two sets of

values. Nevertheless, there are certain disadvantages inherent in the use of antipyrine: It equilibrates slowly with abnormal fluid deposits, such as ascites; it is selectively bound by protein; and it is metabolized at a rate which varies between subjects. Even so, by employment of suitable corrections an estimate of body water can be made.

Deuterium oxide (heavy water) was first used for the determination of body water by von Hevesy and Hofer, in 1934.[12a,b] It should prove an ideal tracer for water. There is no evidence that it is chemically identifiable by the body tissues, the heavy hydrogen equilibrates rapidly with body water, it is not selectively stored or excreted, and in the amounts used it is not toxic to the organism. Moore [12c] introduced its use in the United States in 1946. He and others [16] have shown in desiccation studies that the volume of dilution of deuterium oxide corresponds closely to the total body water.

The measurement of total body water with deuterium oxide is accomplished as follows. A measured quantity of the isotope (usually 25 to 50 gm. of 99.8% deuterium oxide diluted to 100 ml. with 0.85% sodium chloride solution) is injected intravenously, a minimum of one and a half hours is allowed for equilibration of the deuterium with body water, and a blood specimen is then drawn for analysis. The plasma water is first purified by appropriate distillation, and the distillate is then analyzed for deuterium concentration by an elaborate falling drop technique.[17] This method for the determination of deuterium concentration, accurate under optimal conditions to from one to two parts per million, consists of three essentially separate components. The first is an extremely sensitive thermoregulator that maintains the temperature of the water bath to within approximately 0.001 C. The second is an elaborate pipet mechanism that delivers a drop of constant size. The third is a distillation process that achieves a very high degree of purification of plasma water.

INFORMATION DERIVED FROM BODY WATER MEASUREMENTS

Body Water and Body Fat.—At the time his studies establishing the relationship between body specific gravity and body fat were reported, Behnke proposed, on a theoretical basis, that body water and body fat must bear an inverse relationship to each other. To test this concept, we [12d] selected a group of healthy adult male and female human subjects ranging in size from the very lean to the very obese. Heavy water was injected intravenously and, after equilibration with the body water, the concentration of deuterium oxide in the water distilled from plasma samples was measured by means of the accurate specific gravity method described above. The leanest male subject had a total body water value of 71% of body weight (44.5 liters), and the most obese male subject had a total body water value of 42% (48.3 liters). Similarly, the leanest female subject had a total body water value of 68% and the most obese female subject a body water value of 50%. However, the most obese female subject was not clinically as obese as the most obese male subject. In general, the values for percentage body water of female subjects appeared to be somewhat lower than those for male subjects of corresponding weight and habitus. The average value for body water for eight healthy men was 60% of body weight. The subjects who individually had values in the neighborhood of 60% were merely of good nutrition, being neither skinny nor fat.

Other workers have reported somewhat different values for body water. Using antipyrine, Soberman and his associates [14] obtained values for body water in normal subjects ranging from 43% to 58%, and these findings agreed well with those afforded by deuterium and specific gravity measurements. It is not clear whether an attempt was made to select subjects with a wide range of body weight and habitus. In a more recent study, Osserman and his co-workers compared the body specific gravity and antipyrine methods in a group of healthy young men of increasing degrees of obesity. They found that the body water ranged from 43% in the most obese to 72% in the leanest, and these values compare very favorably with those obtained by us (42% and 71%, respectively). These workers found, also, that the value for total body water was almost constantly 71% of the lean body mass. Schloerb and his associates [18] have reported an average value of 61.8% for body water in healthy young adult men and 51.9% in healthy young adult women. Again, these findings correspond very closely with the average of 60% in males and 55% in females found by us. It therefore becomes necessary to revise our concepts concerning the average percentage value for the body water content in healthy adults. The commonly used value of 70% is acceptable only in the unusually lean subject.

The concept of the lean body mass may prove useful clinically. Schloerb and his co-workers [18] found the total body water to be more closely correlated with surface area and oxygen consumption than with the other physical indexes examined. While it would be erroneous to assume that fat is metabolically inactive, it is probable that the lean body mass is metabolically more active. Thus, if the lean body mass can be used as a basis for a comparison of the metabolic activity of different subjects, it may be possible to adjust certain hitherto perplexing "discrepancies" in basal metabolic rates. Projecting this line of thought further into the clinical field, it would seem more reasonable to calculate dosages of drugs on the basis of the lean body mass than on body

weight, as is now so frequently done. The markedly obese patient should not receive powerful drugs on a dosage schedule based purely on body weight. It would be preferable to employ some such convention as the "ideal" body weight.

BODY FLUID COMPARTMENTS

Hardy, Sen, and Drabkin [19] have examined the relationships of total body water, "extracellular" fluid, and plasma volume in eight healthy male subjects selected to cover a wide range of body fat content. Levitt and Gaudino,[20] Steele,[6] and Schloerb and his associates [18] have also examined these body fluid compartments. Although numerous materials have been employed to measure the "extracellular" fluid by the dilution method (among them thiocyanate, bromide, sodium, chloride, and inulin) only sodium thiocyanate and inulin have had wide use. Inulin is generally accepted as perhaps the most reliable substance thus far used for this purpose. It yields values for extracellular fluid in the neighborhood of 15% of body weight.[5] However, the analytical procedures involved in the use of this material render it impractical for general use. The use of sodium thiocyanate,[21] on the other hand, while subject to certain objections, has the solid merit of being readily available and its analysis in body fluids is a simple precedure. Thus, it is easily applicable clinically. The chief disadvantage of using sodium thiocyanate is that a fraction of the thiocyanate ion unquestionably enters the cells in normal subjects, and in certain pathological states this intracellular fraction may be very large.[22] Obviously, any appreciable loss of thiocyanate ion into the cells will result in a value for the extracellular fluid that is erroneously high. Nevertheless, for practical reasons we have employed sodium thiocyanate to estimate the extracellular fluid in normal subjects.[19] Thiocyanate space was found to be more closely correlated with body water than with body weight. Two very lean male subjects both had "extracellular" fluid values of 22% of actual body weight and 32% of total body water. These two subjects had total body water values of 69% and 71%, respectively, of body weight. The most obese male subject, on the other hand, had a thiocyanate space that was only 16% of the body weight but was 38% of the body water. The body water was only 42% of the body weight. Thus, the thiocyanate space represented a greater fraction of the total body water in the obese than in the very lean subjects. The explanation for this is not apparent. We know of no evidence that equilibration of sodium thiocyanate is less complete in the obese than in the lean subject. The possibility of a greater penetration of the fat cells by the thiocyanate ion was considered. Neutral fat within other cells of the body in the obese person might conceivably displace cellular water and thus augment the relative size of the extracellular volume. Finally, the space between the fat cells themselves would be available for extracellular fluid. More quantitative information concerning the "extracellular" fluid would be of substantial aid in estimating fluid replacement in states of dehydration, particularly since this fluid compartment is more rapidly depleted in disease states than is the intracellular fluid.

To preserve an open mind, it is important to think of the fluid compartments as physiological rather than anatomic entities. The use of radioisotopes has greatly altered previous concepts concerning the permeability of the cell membrane to certain electrolytes, particularly sodium, potassium, and chloride. It is now realized that these ions can, under appropriate physiological conditions, cross the cell membrane readily.

Plasma volume has been studied more intensively than has any other body fluid compartment. Yet, a dependable clinical guide for estimation of what the normal plasma volume of a given subject should be is still not available. Because of the unacceptability of values obtained for the plasma volume of normal persons when body weight was used as the basis for calculating this value, a study [18] was made of the correlation between plasma volume and total body water in a group of healthy adult men of widely different degrees of obesity. Plasma volume ranged from 2.75% (in the very fat) to 5.65% (in the very lean) of body weight, with a mean of 4.24% and an average deviation of 22%. Expressed as a percentage of total body water, however, plasma volume ranged from 6.2% in the most obese to 7.8% in the leanest, with a mean of 6.96% and an average deviation of 7%. Thus, plasma volume would appear to be more closely correlated with body water than with body weight.

DYNAMICS OF WATER FUNCTION

The measurement of body fluid compartments has been only one of the avenues of research opened by the availability of a satisfactory tracer element for water. Such studies may be characterized as "static" in nature. There are other types of investigation that are aimed at illuminating "dynamic" or "kinetic" aspects of water metabolism. As an example, one may cite determinations of the half-time or biologic half-life of a molecule of water in the body. By administering deuterium oxide orally and measuring rates of urinary excretion, von Hevesy and Hofer [12a] estimated that the length of time the average molecule of water remained in the body of their subject was approximately nine days. In a single subject, one of us (J. D. H.)[23] found this period to be 11 days, and in a number of subjects Schloerb and his co-workers [18] arrived at an average figure of 9.3 plus or minus 1.5 days. Clearly, however, this figure must necessarily be influenced by rates of water ingestion and excretion; that is, the more rapid the water turnover in the body, the shorter is the time the average molecule of water will remain in the body. Accordingly, one would expect the half-times to be different in warm and cold climates and to be abnormal in patients with febrile illnesses, uncontrolled diabetes mellitus, and thyrotoxicosis.

Body Weight Changes in Surgical Patients.—Even momentary reflection suggests that the rapid weight loss that follows many surgical procedures must often represent simple water and salt excretion. One of us (J. D. H.) has recently studied a patient who was admitted to the hospital in a state of extreme weakness and emaciation whose diagnosis was that of simple esophageal diverticulum with severe dysphagia.[24] Before treatment was begun her weight was 69 lb. (31.3 kg.) and her body water value was 22 liters. She was then tube fed for 17 days. During this time her general condition and appearance improved enormously, and her weight increased to 86 lb. (39 kg.). Immediately prior to successful surgery, her body water was again determined with deuterium oxide and was found to be 29 liters. Thus, despite the fact that clinical edema was not manifest, her weight gain consisted very largely of water. This single example is cited to indicate the relatively large variations in body water content that may escape clinical detection.

[23] Hardy, J. D.: The D_2O Dilution Space as a Measure of Total Body Water, and the Relation of Body Fluid Compartments to Body Fat and to Each Other, Thesis, Graduate School of Medicine, University of Pennsylvania, 1951.

Heart Failure.—Rates of water mobilization and distribution in cardiac decompensation offer a fertile field for investigation. In such patients the normal relationships between percentage body water and body weight do not hold. For example, we have determined the body water of frankly edematous patients and found their percentage of body water no greater than that in healthy lean subjects. The explanation of this lies, of course, in the fact that these patients were somewhat obese. If some simple means of determining their body fat content were available it would be found that their percentage of body water was appreciably greater than 71% of the lean body mass.

Other Factors That May Be Examined with Deuterium Oxide.—Rates of spinal fluid formation may be studied with the use of heavy water as a tracer. Fluid kinetics in thermal burns and shock represent one of the most important factors associated with the management of these injuries, and several surgical clinics are actively investigating these problems. The relationships between the blood supply of the bowel and the movement of water and electrolytes across its cellular membranes will surely be subjected to a more quantitative scrutiny than has been possible in the past.

SUMMARY

The several types of measurements that may be employed for the determination of total body water are outlined. The use of dilution methods has made available valuable information concerning the relation of body fluid compartments to body fat and to each other. Deuterium oxide (heavy water) appears to be an excellent tracer substance for water, and its availability has made possible a more critical examination of rates of water turnover in the body and rates of transfer of water across various cell membranes. It is reasonable to anticipate that our knowledge of body fluid compartments and of water kinetics in the human body will be enormously extended by the use of isotopes.

INCREASED INTRACRANIAL PRESSURE IN EMPHYSEMA CAUSED BY OXYGEN INHALATION

John C. Mithoefer, M.D., Cooperstown, N. Y.

Respiratory depression followed by delirium and coma has developed in several patients with chronic pulmonary emphysema while they were receiving oxygen therapy in this hospital. I have studied some of these patients as well as some normal subjects in an effort to determine the mechanism of production of this phenomenon.

Three normal subjects and four patients with chronic lung disease were studied. Their ages and diagnoses are listed in table 1. Brief summaries of the clinical states of the four diseased patients are given below.

PROCEDURE

The subject lay on his left side, and an indwelling needle was placed in the brachial artery. A lumbar puncture needle was inserted, connecting the subarachnoid space to a spinal fluid monometer. The subject breathed through a rubber mouth piece attached to a three-way valve by which connection could be made either to a 9L spirometer containing 100% oxygen or to room air. During an initial period of rest and room air breathing, basal spinal fluid pressure readings were obtained. The mouth piece valve was then turned to connect the subject to the spirometer that contained 100% oxygen, and a soda lime-carbon dioxide absorber. An attached kymograph recorded the respiratory excursions. Spinal fluid pressures were recorded every 30 seconds throughout all procedures. When the effect of oxygen inhalation had been observed, the valve was again turned to give the subject access to room air. The carbon dioxide absorber was then removed from the spirometer and the tank refilled with 100% oxygen. When the valve was again turned, the subject was made to rebreathe oxygen from the spirometer, which, lacking a carbon dioxide absorber, came gradually to contain increasing tensions of carbon dioxide. The spirometer gas was analyzed[1] at the end of rebreathing and found in all the carbon dioxide experiments to contain 6 to 8 vol.% of carbon dioxide. At appropriate intervals throughout the procedures, arterial blood samples were drawn with care being taken to exclude oxygen and stored in ice[2] until they were analyzed for oxygen and carbon dioxide in the Van Slyke manometric apparatus.[3]

From the Cardiac Laboratory, The Mary Imogene Bassett Hospital.

RESULTS

Ventilation (Table 2).—During oxygen inhalation the three normal subjects had an average increase in respiratory volume of 15% and a 16% increase in tidal volume. This slight increase in ventilation produced by oxygen in normal subjects is consistent with the findings of others.[4] Patients L. K. and J. W. showed slight increase in minute volume during oxygen inhalation, while the tidal volume of one decreased and that of the other increased slightly. There was no significant change in the carbon dioxide content of their arterial blood, which initially had been normal. Both subjects appeared to be consciously controlling their respirations during the procedure.

Patients J. H. and K. B. showed a prompt decrease in both minute volume and tidal volume during oxygen inhalation. The change in minute volume was less than the decrease in tidal volume, owing to a slight increase in respiratory rate. The arterial carbon dioxide content was abnormally high in both subjects initially (58 vol.%). It rose to 65 vol.% in K. B. during oxygen inhalation. A second blood sample was not drawn from J. H.

Table 1.—*Data in Cases Studied*

Subject (Sex)	Age, Yr.	Diagnosis
Normal 1 (F)	18	Convalescent from poliomyelitis; heart and lungs normal
Normal 2 (F)	64	Convalescent from cerebrovascular accident; heart and lungs normal
Normal 3 (M)	32	Convalescent from poliomyelitis; heart and lungs normal
Patient J. H. (F)	55	Cor pulmonale secondary to pulmonary fibrosis and emphysema
Patient K. B. (F)	65	Chronic obstructive emphysema secondary to bronchial asthma
Patient L. K. (M)	70	Chronic obstructive emphysema secondary to bronchial asthma
Patient J. W. (M)	71	Chronic obstructive emphysema secondary to bronchial asthma

Table 2.—*Effect of 100% Oxygen Inhalation on the Respiration of Normal Subjects and Patients with Chronic Lung Disease*

	Minute Vol. (Cc.) During First Minute	Minute Vol. (Cc.) at Time of Maximum Change	Change in Minute Vol., %	Tidal Vol. (Cc.) First Minute	Tidal Vol. (Cc.)	Change in Tidal Vol., %
Normal 1	4,500	5,000 (3 min.)	+11	300	340 (3 min.)	+13
Normal 2	5,000	5,700 (5 min.)	+14	240	265 (5 min.)	+10
Normal 3	6,080	7,260 (7 min.)	+19	380	480 (7 min.)	+26
Patient J. H.	5,000	2,750 (12 min.)	—45	340	170 (12 min.)	—50
Patient K. B.	3,920	3,160 (7 min.)	—19	216	110 (7 min.)	—49
Patient L. K.	10,500	11,000 (6 min.)	+10	585	502 (6 min.)	—14
Patient J. W.	7,500	8,500 (11 min.)	+13	418	439 (11 min.)	+ 5

Spinal Fluid Pressure.—The three normal subjects and patients L. K. and J. W. showed no significant change in spinal fluid pressure during oxygen inhalation (fig. 1).

The other two patients, J. H. and K. B., had, while breathing oxygen, a prompt, steady rise in spinal fluid pressure to over 600 mm. and 500 mm. of water, respectively. Both of these patients had elevated spinal fluid pressures initially and were the subjects in whom respiratory depression occurred, as described above. The spinal fluid pressure slowly began to fall toward its initial level when the oxygen inhalation was stopped in patient J. H. but was elevated again by the inhalation of 6% carbon dioxide. In patient K. B. the high spinal fluid pressure was rapidly reduced to a level below its initial pressure by hyperventilation with 100% oxygen. The patients had no symptoms or change in mental status during the acute elevations in spinal fluid pressure produced in these experiments.

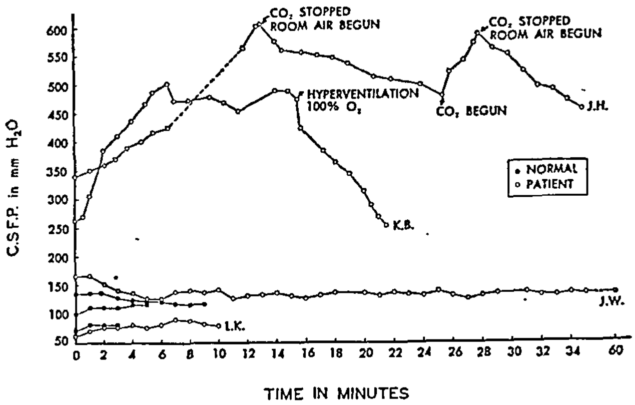

Fig. 1.—Effect of 100% oxygen inhalation on the cerebrospinal fluid pressure of patients with pulmonary emphysema and on normal subjects.

Figure 2 shows the effect of the inhalation of 6% to 8% carbon dioxide on the spinal fluid pressure of the three normal subjects. Carbon dioxide produced a rise in spinal fluid pressure to high levels. The rate of rise in pressure paralleled the accumulation of carbon dioxide in the spirometer during rebreathing. The pressure fell promptly to normal or below when carbon dioxide inhalation was discontinued. Except for an increase in respiratory minute volume, these subjects had no symptoms during these procedures.

REPORT OF CASES

Case 1.—Patient J. H., a 55-year-old housewife, was admitted to the hospital in 1949, with a history of frequent attacks of bronchial asthma for the previous 22 years. Two years before admission her asthma became more severe, and she began to notice cyanosis and a florid complexion. She had frequent headaches, dyspnea on exertion, unproductive cough, paroxysmal nocturnal dyspnea, and diminution of vision. Physical examination at that time revealed a moderately cyanotic woman in respiratory distress. There were bilateral papilledema, signs of

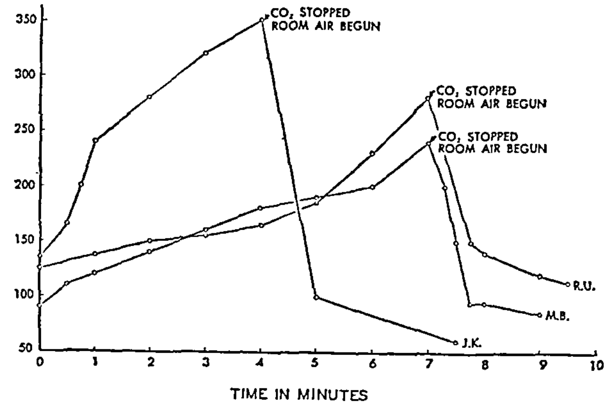

Fig. 2.—Effect of 6% to 8% carbon dioxide inhalation on the cerebrospinal fluid pressure of normal subjects.

[4] Dripps, R. D., and Comroe, J. H., Jr.: The Effect of Inhalation of High and Low Oxygen Concentrations on Respiration, Pulse Rate, Ballistocardiogram and Arterial Oxygen Saturation (Oximeter) of Normal Individuals, Am. J. Physiol. 149: 277, 1947.

pulmonary emphysema, and congestive heart failure, with enlargement of the left ventricle and pulmonary conus seen on x-ray. Her blood pressure was 172/110, hemoglobin 20.6 gm. per 100 cc., red blood cell count 6,590,000, and venous pressure 16 cm. of water.

She was readmitted in October, 1949, at which time her clinical condition was essentially as before. A lumbar puncture showed an initial pressure of 350 mm.; manometric studies were normal. The spinal fluid protein, chloride, and sugar levels were also normal. There was electrocardiographic evidence of right ventricular hypertrophy. Her arterial oxygen saturation was 11.7 vol.% and carbon dioxide content 40 mEq. per liter. She was treated for bronchial asthma and had several phlebotomies.

She was again admitted in October, 1950, because of a severe asthmatic attack. Because of her intense cyanosis, she was given 100% oxygen by nasal catheter shortly after admission. The cyanosis disappeared after a few minutes, but she soon became lethargic and after seven hours of oxygen therapy lapsed into deep coma. Her respirations were shallow. The oxygen therapy was slowly discontinued, and she concomitantly regained consciousness. It was because of this episode that procedures described in this paper were performed.

During the past year this patient has gotten along well on restricted activity and treatment for asthma. The secondary polycythemia has required occasional phlebotomies.

Case 2.—K. B., a 65-year-old housewife, was admitted to the hospital in November, 1950, with the chief complaint of asthma of 36 years' duration. Her asthma began at the age of 29, after which she had intermittent attacks but was free of symptoms between them. Five months before admission, after an upper respiratory infection, an asthmatic attack started, which continued more or less uninterruptedly and brought about her admission to the hospital.

She presented physical signs of pulmonary emphysema. There were expiratory wheezes heard throughout both lung fields. There was slight cyanosis. Her vital capacity was 850 cc., venous pressure 11 cm. of water, circulation time 24 seconds, hemoglobin 16 gm., red blood cell count 5,890,000, and venous carbon dioxide content 29 mEq. per liter. Fluoroscopic examination of the heart showed generalized enlargement, with abnormally prominent pulmonary vessels. The patient's cerebrospinal fluid pressure response to oxygen inhalation was measured on her eighth hospital day, at which time her asthmatic attack had ended.

Case 3.—L. K., a 65-year-old retired farmer, was seen in October, 1950, because of a severe asthmatic attack of four days' duration. He had had bronchial asthma for many years. There were physical signs and roentgenographic evidence of obstructive emphysema. His heart was of normal size, and there were no signs of congestive failure. His carbon dioxide content and hemoglobin were normal. He was treated for asthma, after which he became symptom-free, except for exertional dyspnea. The studies reported were done five months later.

Case 4.—J. W., a 71-year-old retired farmer, was admitted to the hospital for the 11th time in October, 1950, because of a severe asthmatic attack. Bronchial asthma began at the age of 20. In recent years he had had frequent attacks, between which he was incapacitated by pulmonary insufficiency. In addition to physical signs of bronchial asthma and obstructive pulmonary emphysema, he had roentgenographic evidence of numerous large emphysematous blebs arising from the upper lobe of the left lung. There was no cardiac enlargement or signs of congestive failure. Laboratory findings were as follows: hemoglobin 14 gm. per 100 cc., red blood cell count 5,240,000, and carbon dioxide content 46 mEq. per liter. He was treated for asthma and discharged from the hospital. In December, 1950, the studies reported here were performed. He was apprehensive during the procedure and seemed to be voluntarily controlling his respirations.

COMMENT

Undesirable effects of oxygen inhalation in certain patients with pulmonary disease have been reported by others.[5] Barach [5a] described mental confusion and coma occurring in patients with chronic hypoxia when they were given high concentrations of oxygen to breathe. His patients all recovered consciousness, in spite of the continued oxygen therapy. Davies and Mackinnon [5c] described neurological signs, coma, and death with elevation in the spinal fluid pressure during oxygen therapy in certain patients with cor pulmonale. Comroe and coworkers [5e] studied the effects of oxygen on 65 chronically anoxemic patients; mental changes ranging from somnolence to coma occurred in nine. These patients showed diminished ventilatory volume, increased arterial pCO_2, and acidosis during oxygen therapy. Beale and co-workers [5f] reported respiratory acidosis and coma produced by oxygen administered to a patient with asthma but without pulmonary emphysema or fibrosis.

The inhalation of high concentrations of oxygen in normal subjects depresses respiration slightly during the first two minutes; there then follows an increase in minute volume probably owing to the irritant effects of oxygen in high concentration.[4] Table 2 shows the respiratory stimulation that occurred in our normal subjects. An initial depression was not demonstrable, since a preceding spirometric record of room air breathing was lacking.

In two of the subjects with pulmonary emphysema, J. H. and K. B., the 50% decrease in tidal volume during oxygen inhalation is abnormal. It indicates that in these patients anoxia was an important respiratory stimulant, which, acting presumably through the aortic and carotid chemoreceptors, had assumed much of the function of stimulation normally carried by carbon dioxide and the medullary centers. When the anoxic stimulus was removed by oxygen inhalation, respiratory depression ensued in spite of a rising arterial carbon dioxide tension. This is reminiscent of the suppression of carbon dioxide sensitivity of the respiratory centers by barbiturates and consequent respiratory depression produced by oxygen administration in patients poisoned by these drugs.[6]

Patients with chronic pulmonary emphysema are characteristically less sensitive than normal to the respiratory stimulus from carbon dioxide [7] and often have respiratory acidosis from carbon dioxide retention without an increased respiratory rate. This insensitivity of the respiratory centers may be reversible, at least in some cases. This is suggested by Beale's [5f] case of asthma without chronic lung disease and by the fact that Barach's [8] patients did recover from respiratory depression and coma caused by oxygen inhalation in spite of continued oxygen administration. These observations further suggest that carbon dioxide insensitivity may be promoted by anoxia.

Carbon dioxide inhalation dilates cerebral blood vessels,[9] increases cerebral blood flow,[10] spinal fluid pressure,[11] and increases the rate of spinal fluid secretion.[12]

We have demonstrated, as did Davies and Mackinnon,[5c] that the carbon dioxide retention in these patients increases the intracranial pressure as does carbon dioxide inhalation in normal subjects. We interpret this as the result of increased cerebral blood flow from vasodilatation. The assumption of increased cerebral flow on the basis of measurements of increased intracranial pressure is justified under the acute circumstances of these experiments.[13]

The demonstration of increased intracranial pressure in these patients does not explain the production of their mental changes. There are, however, reports of experiments that suggest the explanation of these changes and illustrate the complexity of the problem.

In patients with increased intracranial pressure from brain tumor, there is a critical level of cerebrospinal fluid pressure beyond which cerebral blood flow and cerebral oxygen consumption decrease and coma ensues.[14] This level is 450 mm. of water. Below it the increased cerebral vascular resistance that results from the raised intracranial pressure is compensated for by reflex increase in mean arterial blood pressure; cerebral metabolism and consciousness are thereby maintained. Oxygen inhalation in J. H. and K. B. resulted in cerebrospinal fluid pressures above this critical level. We therefore cannot dismiss the possibility that coma may have resulted from diminished oxygen utilization as a result of the high intracranial pressure per se. If so, the diminished cerebral oxygen consumption and mental changes are in part a function of the duration of intracranial pressure increase, because Patterson and co-workers [10c] found that patients with pulmonary emphysema have a high cerebral blood flow and low cerebral oxygen consumption. When the patients were given high concentrations of oxygen to breathe for 30 minutes, their cerebral blood flow increased without change in cerebral oxygen consumption or mental status. Since the coma that occurs in patients with emphysema who have been given oxygen takes hours to develop, the short duration of their experiments makes them inconclusive.

Kety and Schmidt [10b] have studied the effects of 5% to 7% carbon dioxide and 10% oxygen inhalation for 15 to 30 minutes on the cerebral metabolism of normal subjects. Both hypercapnia and anoxia produce a fall in cerebral vascular resistance and consequent rise in cerebral blood flow. These changes occurred without any fall in cerebral oxygen consumption in the face of the development of mental changes. This surprising result illustrates the complexity of the problem of cerebral function, and the authors state:

> The conclusion is apparent that the higher psychic functions are associated with biochemical changes so subtle and complex as to render any attempt to describe them in terms of mere oxygen utilization no more adequate than to predict the fidelity of a radio by its power requirements.

Studies on cerebral metabolism in diabetic acidosis and coma [15] showed certain relationships between cerebral metabolism and function that are applicable here. Patients in diabetic acidosis without coma have a slightly increased cerebral vascular resistance and decreased cerebral blood flow. In those patients in coma the cerebral vascular resistance is diminished and the cerebral blood flow increased. The greatest difference between these two groups is in cerebral oxygen consumption, which, although depressed in both groups, is much lower in comatose patients. There is a critical level of cerebral oxygen consumption of 2.1 cc. per 100 gm. of brain tissue per minute (normal, 3.3 cc. per 100 gm. per minute), at or below which unconsciousness occurs. The cerebral oxygen consumption is almost completely unrelated to the cerebral blood flow but is well correlated with arterial pH. This suggests that in patients with emphysema and carbon dioxide retention the fall in pH that accompanies hypercapnia may after sufficient time diminish cerebral oxygen consumption by interference with its utilization and effect coma in spite of a greater than normal oxygen supply delivered to the brain.

Other possible mechanisms that have been discussed [5e] are carbon dioxide narcosis, cerebral vasospasm, reflex cerebral depression from high oxygen tension, or direct cerebral depression from oxygen.

We have demonstrated that the intracranial pressure increase is not the result of high oxygen tension itself. K. B. (fig. 1), in whom the spinal fluid pressure was lowered by hyperventilation with 100% oxygen, illustrates this and suggests a method of prevention, namely, that patients with ventilatory insufficiency who need oxygen in high concentrations be encouraged to breathe deeply. If they are conscious and cooperative, this can be accomplished by frequent reminder from an attendant at the bedside for a period long enough to tide the patient over an emergency. If they are not able to follow the directions for breathing given by an attendant, then artificial respiration should be given. In case they do not need high concentrations of oxygen from the start of therapy, following Barach's plan [5e] of gradually increasing the concentration of inhaled oxygen over a period of days would suffice. Unfortunately, one cannot predict with certainty which patients with pulmonary emphysema will suffer the adverse effects of oxygen; therefore all such patients should be under close supervision and their mental status determined at frequent intervals.

SUMMARY

1. In some patients with pulmonary emphysema the administration of high concentrations of oxygen results in mental changes ranging from somnolence to coma and sometimes death.

2. The effect of oxygen and carbon dioxide inhalation on the pulmonary ventilation and spinal fluid pressure of four patients with chronic pulmonary emphysema and three normal subjects has been studied in an effort to elucidate the mechanism of production of this phenomenon.

3. The inhalation of carbon dioxide by normal subjects increases the spinal fluid pressure through cerebral vasodilatation. In two of the patients with pulmonary emphysema, oxygen inhalation resulted in respiratory depression, carbon dioxide retention, and increased intracranial pressure.

4. The possible mechanisms for the production of this sequence of events and the mental changes in these patients are discussed.

5. Occasional periods of hyperventilation during oxygen therapy will prevent the development of these undesirable effects.

LATE RESULTS OF ARTIFICIAL PNEUMOPERITONEUM IN PULMONARY TUBERCULOSIS

TEN YEAR FOLLOW-UP STUDY OF TWO HUNDRED PATIENTS

Everett Morris, M.D.
and
Emil Bogen, M.D., Olive View, Calif.

Early results of the use of artificial pneumoperitoneum in the treatment of 200 patients during recent years were reported by Dr. Edwin S. Bennett in April, 1938.[1] From his experience, he concluded that this procedure should be used in the treatment of several groups of patients, which he described. The present paper reviews the status of the same 200 patients 10 years after pneumoperitoneum in order to determine the usefulness of this treatment. Twenty-seven physicians participated in this series of treatments, in which there were no fatalities directly attributable to the treatment. Most of the patients had a poor prognosis before pneumoperitoneum. In almost 90%, the disease was far-advanced, and abundant tubercle bacilli were usually found in the sputum. Other forms of collapse had been tried unsuccessfully in all but nine of the patients. Artificial pneumothorax had been attempted in 90% of the patients. This procedure was often repeated, and it was usually found that there was no free space or only a small, ineffectual collapse. Phrenic paralysis, usually temporary, had been performed in 172 patients, and 3 of these patients had a thoracoplasty operation before the pneumoperitoneum.

The average period of sanatorium care before the pneumoperitoneum was nearly a year. The average duration of the pneumoperitoneum until discharge from the sanatorium was 7.3 months, but many patients continued the treatment with refills after discharge, for from 1 to 40 months. The refills done at the sanatorium averaged 800 cc. of air, and the average interval between refills was one week. In several instances in which, for various reasons, pneumoperitoneum had been abandoned, it was reestablished without difficulty. Pneumoperitoneum had been established in several patients on whom, some years previously, abdominal operations had been performed, after which there had been drainage for a period of months.

Complications that caused marked discomfort and led to discontinuance of treatment arose in 20 patients, or 10% of the cases. In three instances, pneumoperitoneum was discontinued because of the appearance of hernia, although in several other patients, the hernia did not necessitate cessation of treatment. Four patients complained of immediate extreme, but transitory, epigastric and shoulder pain. Today, the latter symptom is considered a favorable prognostic sign. Two patients had extensive subcutaneous emphysema. In seven patients, pronounced distention of the abdomen developed the day after refills were administered; this can be ascribed either to meteorism or to peritoneal effusion. Two patients had pronounced abdominal adhesions that were visible on the roentgenogram, and, in three patients, fluid developed to a degree that required aspiration. In another patient the procedure had to be discontinued because of obliterative peritonitis. A total of 31 patients suffered from hydropneumothorax prior to the initial pneumoperitoneum, and, it developed in 8 more after treatment was begun.

Free fluid, usually clear but occasionally turbid, was found in the abdomen in over half of the 20 patients on whom autopsies were performed, varying from 150 to 1,500 cc. in volume. In addition, a plastic exudate covering the viscera and matting together the coils of the intestines was found in two patients. In other patients, more organized reactions appeared in the form of fibrotic plaques or thickening, which were usually discrete and scattered but were occasionally confluent and extensive, covering the exposed viscera entirely. Although autopsy often revealed considerable peritoneal fluid or thickening, no such observation was made in the five patients on

---

From the Olive View Sanatorium.

[1] Bennett, E. S.: Induced Pneumoperitoneum in the Treatment of Pulmonary Tuberculosis: Review of 200 Cases at Olive View Sanatorium, Journal-Lancet 58: 187 (April) 1938.

whom laparotomies were performed during the course of the artificial pneumoperitoneum, and, postoperatively, all the patients had the pneumoperitoneum reestablished.

At the time Dr. Bennett made his report, in 1938, 27 of the 200 patients had died in the sanatorium, and 5 others had died after discharge. Since then, an additional 17 patients have died in the sanatorium, and 61 more died after their discharge, making a total of 110 deaths (55% of the group).The data on all the patients have been reviewed in order to determine whether any prognostic indexes could be found in this material.

The patient's race appears to have little influence on the course of the disease, the fatality rates being, 58% of the 106 white patients, 51% of the 71 Latin-Americans and Mexicans, and 52% of the 23 colored patients, who were chiefly Negroes. There were 48 deaths among the 93 males, about 52% of the group, as compared with 62 deaths among the 107 females, or 58%. There was little difference in the course of the disease in the various age groups, the average age being 28 years in both the survivors and those who died.

Associated phrenic paralysis appeared to have a beneficial influence in this series, the fatality rate being only 44% of the 15 patients who had such operations both before and after the induction of pneumoperitoneum and 49% of the 60 patients who had phrenic paralysis before pneumoperitoneum was instituted. This compares favorably with a fatality rate of 64% among those in whom the phrenic was paralyzed some time after pneumoperitoneum, and 84% of the 26 patients who did not have phrenic paralysis. Although there were numerous exceptions, it appeared, in general, that the patients in whom the paralyzed diaphragm rose more had, in this series, a somewhat lower, later fatality rate. The average rise of the diaphragm in the patients with phrenic paralysis was about 4 cm.

Cavities were found in the lungs in all but seven patients, and the prognosis was, in general, worse when there was larger, multiple, or bilateral cavitation, but the position of the cavities, whether they were in the upper or lower part of the lungs or whether they appeared to be central or peripheral on the roentgenogram, did not seem to affect the later fatality rates. The erythrocyte sedimentation rate was greatly accelerated in almost all patients, but, in general, the sedimentation rate was somewhat slower in those who survived and slowed more after institution of the pneumoperitoneum.

The severity of the disease may be indicated by the abundance of tuberculous complications clinically recorded prior to the institution of artificial pneumoperitoneum, including 39 cases of pleural effusion, with nine empyemas and four chest wall abscesses with one broncho pleural fistula, 36 cases of tuberculous enteritis with 10 tuberculous appendixes, 9 cases of tuberculous fistulas, 34 cases of tuberculous laryngitis, and 13 cases of tuberculous tracheobronchitis. Many more complications existed, but these were not recorded, as was indicated by the autopsies of the 20 who were examined.

In only 18 patients was the disease apparently arrested or arrested at the time of discharge from the sanatorium, and in 30 other patients it was said to be quiescent. Only 11 (23%) of these patients died subsequently. On the other hand, of the 72 patients discharged as "improved" and the 36 discharged as "worse," 55 (50%) have died.

Of the 200 patients in this series, pneumoperitoneum was induced in 35 for intestinal or peritoneal disease, of whom 23 (66%) died and 34 for tuberculous infiltration or pneumonias, of whom 19 (56%) died. A total of 74 patients were treated for cavities, of whom 36 (48%) died, and 56 were given pneumoperitoneum for symptomatic relief only, of whom 31 (55%) died. In comparing the early clinical results with the indications, it was concluded that the pneumoperitoneum had some desirable effect in only 65 (33%) of the patients, among whom only 20 (31%) died later, whereas, among the 135 in whom it had been entirely ineffective, 90 (68%) had died.

Pneumoperitoneum was terminated by death in 24 patients and because of discomfort or abdominal fluid in 28 patients; it was discontinued to allow more definite therapeutic measures in 20 patients. In 33 patients, it was abandoned as obviously ineffective, and in 87 it was still being given at the time of discharge from the sanatorium. In only one patient was pneumoperitoneum discontinued, while he was in the sanatorium, as an unqualified success, no longer needed; however, to this success should be added the 20 patients in whom, after pneumoperitoneum, thoracoplasty or other surgical measures that could not have been previously used were found feasible. A study of this group of 20 patients shows that 5 patients were unimproved or grew worse; 6 were improved; 1 case was quiescent; 1 patient worked for two years and 7 have been working for seven to nine years.

Ten years after most of the patients received their initial pneumoperitoneum, only 38 patients (40%) of the 90 living, reported that they were able to work. Many of these were enthusiastic over the benefit that they believed they had received from the treatment, and the physicians were often pleasantly surprised by the unexpected favorable results.

Of the 90 now living, 7 had arrested cases on discharge; 8 had apparently arrested cases; 22 had quiescent cases; 24 had improved cases; 24 had unimproved cases; and 6 deserted or left against medical advice. The reports made by our follow-up workers show that they were engaged in varied economic activities, ranging from the duties of a housewife, in some cases limited, to a full-time truck driver's job.

The incidence of survival, improvement, and recovery after induced pneumoperitoneum treatment in this series of patients with far-advanced cases is low. While its use in this series of patients would seem to have been justified, the results suggest that pneumoperitoneum should not be allowed to substitute or delay the institution of more direct and effective forms of treatment. It is still felt, however, that this procedure has therapeutic value, which may be more clearly brought out in later series, when it is applied to more favorable forms of the disease, and especially when it is supplemented by chemotherapy and other therapeutic measures.

POSTOPERATIVE BACTERIAL SYNERGISTIC CELLULITIS OF ABDOMINAL WALL

FATALITY FOLLOWING HERNIORRHAPHY

Moses Behrend, M.D.
and
Theodore B. Krouse, M.D., Philadelphia

In this era of antibiotics and chemotherapeutic agents the incidence of postoperative wound infections has been reduce to a negligible percentage. This is due not only to these new agents but also to improvement in the efficiency of personnel, sterilization of instruments and fields, and improved surgical techniques that follow the basic concepts of good surgery and good tissue care. Against this background, there occur, rarely, certain infectious complications of normal surgical treatment. These complications, at first slow-moving, are insidious, relentless, and almost totally resistant to the usual modes of treatment. All concerned, the surgeon, the physician, the bacteriologist, and the pathologist, may well conclude that much is yet to be done in the field of bacteriology in assessing the specific organism or organisms causing such an infection and in determining the best specific therapy to combat them.

All types of chronic gangrene, although characterized by certain differences, are caused by special combinations of organisms. They may be conveniently classified as follows:[1] (*a*) postoperative progressive bacterial synergistic gangrene of the abdominal or chest wall, (*b*) gangrenous impetigo or ecthyma, (*c*) fusospirochetal infection of the skin, and (*d*) amebic infection of the skin. We are concerned with the first type as it affects the abdominal wall. This type of infection, due to an unusual synergism, has been described by Meleney,[2] Mester,[3] Brewer and Meleney,[4] Carroll,[5] Lichtenstein,[6] Dodd,[7] and Bassow.[8] Vier [9] has pointed out that it may be seen but once or twice in the experience of the average surgeon; he states, "... but when it does occur, it is so devastating to patient and distressing to surgeon that one is impressed with the importance of its early diagnosis and treatment." Cultures taken from such a gangrenous area contain microaerophilic nonhemolytic streptococci associated with hemolytic micrococcus pyogenes aureus.

The purpose of this paper is to report a case of a postoperative progressive inflammation of the anterior abdominal wall, in many ways similar to and as distressing as the gangrenous form. The infection was manifested grossly as an intense edematous type of cellulitis, with no evidence of gangrene. An anaerobic Streptococcus and a gram-positive hemolytic aerobic Bacillus identified as B. subtilis were isolated from the tissue. Injection of these organisms in combination into animals produced a similar tissue lesion.

REPORT OF A CASE

A 37-year-old white man was admitted to the Jewish Hospital Nov. 6, 1945, with the chief complaint of a hernia of 20 years' duration. The patient had first noticed a lump in the right groin. This lump had enlarged progressively over the course of years, and for the last 10 years the patient had been wearing a supportive truss. He had no other complaints referable to this local area. There were no gastrointestinal, genitourinary, or musculoskeletal symptoms. None of the other systems were contributory to his condition. The patient had been a regular blood donor and had made donations on 20 occasions prior to this admission. It was believed that these donations were properly spaced (not more frequently than every four to six weeks). Physical examination revealed a well-developed, well-nourished man in no distress and appearing to be in good health, except for the hernia, which he had elected to have removed. The temperature was 97.3 F, pulse rate 80, respiratory rate 20, and blood pressure 105/70 mm. Hg. The head and neck regions were normal, and the heart and lungs were normal. The abdomen was normal, except for the right lower quadrant, in which the right inguinal ring was enlarged. Preoperative laboratory data were as follows: urine normal; hemoglobin, 15.6 gm.; red blood cell count, 5,100,000; white blood cell count, 6,900, with 71% polymorphonuclear neutrophils (96% filamented and 4% nonfilamented), 28% lymphocytes, and 1% monocytes; blood sugar, 94 mg. per 100 cc.; and blood urea nitrogen, 14 mg. per 100 cc.

The preoperative diagnosis was right incomplete inguinal hernia. Two days after admission a Gallie herniorrhaphy was performed, with the patient under spinal anesthesia. Fascia lata strips from the left thigh, obtained with a Matson stripper, were employed in the repair. One gram of sulfadiazine was sprinkled into the wound, and closure was effected with clips. The patient's condition was good when he was returned to his room. In the first 24 hours after the operation the temperature climbed to 102 F and the pulse rate from 80 to 100. The blood pressure was 120/95 mm. Hg. On the ninth postoperative day there was slight tenderness and pain around the incision and the tissue seemed to be firmly indurated and edematous. The temperature at this time was 99.2 F. On the following day, after he had received a total of 160,000 units of penicillin in 21 hours, he was noted to be perspiring profusely and to have a rapid pulse rate. His temperature was normal. On Nov. 19 the wound area was anesthetized with procaine hydrochloride (novocaine®), and the wound was opened and a rubber-dam drain inserted. A culture grown from material taken from the site yielded colonies of aerobic hemolytic, gram-positive bacilli. The broth contained gram-positive streptococci in chains and gram-negative bacilli. The blood culture showed no growth after three days. On the 12th postoperative day the patient stated that he felt weak and

exhausted. He had perspired profusely during the night and had required 10 changes of clothing. He began passing small amounts of urine at frequent intervals. The lower quadrants of the anterior abdominal wall were considerably indurated, had the consistency of leather, and were edematous. This condition extended to the contralateral side. In addition, the penis was remarkably swollen, rendering micturition difficult. The pulse was difficult to palpate, and the blood pressure was 110/100 mm. Hg.

The condition at this time was believed to be an incisional abscess with cellulitis. The incision was reopened and the rubber-dam drain reinserted. There was no evidence of pus, despite the fact that several skin incisions had been made. The attending surgeon was impressed with the tissue consistency and stated that it cut as though it were leather. The patient was put into the position for shock, and administration of plasma and sulfadiazine was begun. Every three hours 30,000 units of penicillin was given. (It was not customary to give massive doses of penicillin at that time.) On the 13th day the patient was unimproved. The areas of induration and edema had advanced cephalad, the pulse was not palpable, and there was no recordable blood pressure. The patient was very apprehensive. He became dyspneic, and within a period of five to eight minutes he became successively more dyspneic, restless, talkative, delirious, and cyanotic. Venesection did not function, the most apparent reason being that intravascular clotting had begun. He was given a mixed gas gangrene antitoxin, 10,000 units intravenously, and an equal dose intramuscularly. He died on the 13th postoperative day.

Autopsy.—At autopsy the tissues in the incision were found to be partly necrotic, grey, and very firm; no pus or odor was noted. There was no evidence of gas formation in the tissues. The entire abdominal wall of the right lower quadrant and the medial third of the left lower quadrant were indurated and swollen. The overlying skin was a mottled purple color. The scrotum and both legs, particularly the right one, were edematous. Opening of the abdominal wall revealed the following condition: About an inch below the umbilicus, there was a sharply demarcated change in the subcutaneous fat underlying the abdominal wall. The tissues were brawny, indurated, and mottled hemorrhages were scattered throughout. The fat was greyish. There was no odor, pus, or gas in the deeper tissues. The rectus muscle on the right was completely involved by this process; it was swollen and greyish, and there were petechiae scattered throughout. The left rectus muscle of the lower quadrant showed early involvement. The preperitoneal fat was also indurated and swollen. The omentum was fatty, and the portion lying in the right lower quadrant seemed firm and edematous; it was exceptionally solid when cut. The terminal ileum was anchored to the pelvis by an abnormal band of peritoneum.

The vessels were essentially normal. The heart weighed 360 gm. and was somewhat flabby. The lungs were firm and congested, without edema, and both weighed 510 gm. The spleen weighed 200 gm. and was flabby, mushy, and dull red on section, with loss of architecture. The lymph nodes were normal. The kidneys weighed 180 gm. The liver weighed 2,660 gm. and was flabby and pale, the cut surface being tan to orange. The pancreas was congested, and the adrenal glands showed decreased cortical lipid. In the skin and subcutaneous tissue there were multiple capillary hemorrhages, with a fibrinous exudate but with no cellular reaction (inflammatory cells). A section from the incision area showed fibrinous exudate with a greater cellular reaction. There was necrosis of the vein and artery in the area of the incision and degeneration of adipose tissue. A section from the rectus muscle showed edema, congestion, necrosis, hemorrhage, and an extensive fibrinous exudate with little or no inflammatory cell reaction. Microscopic examination revealed that an overwhelming toxemia had followed infection of the herniorrhaphy wound, with all vital organs showing severe toxic and degenerative changes.

Bacteriological Observations.—Bacteriological examination at autopsy corroborated the previous observations. An anaerobic nonhemolytic Streptococcus and a gram-positive hemolytic aerobic Bacillus identified as belonging to the species B. subtilis were isolated from material taken from the edematous skin wound. When injected intradermally into guinea pigs and a rabbit, they produced edema and induration of the subcutaneous tissue. Similar effects were observed when a mixture of the cultures was injected into the muscles of guinea pigs.[10]

COMMENT

Postoperative progressive bacterial synergistic gangrene is due, as are the other chronic gangrenes, to the symbiotic action of two or more organisms. This symbiosis seems to develop in the area involved in the operation and probably in tissue that has been altered to favor such complimentary growth. In the case we have described, the predominant feature, in contrast to other lesions that have been described in this anatomic area, was an intense board-like edematous cellulitis rather than a gangrene. In nearly half a century of surgical practice we have never encountered an infection of this type. Although the presence of an anerobic nonhemolytic Streptococcus seemed typical for such an infection, that of its symbiotic mate, a variety of B. subtilis, did not. The family of B. subtilis is recognized to be of low pathogenicity. It is used as a test organism for sterilization procedures.[1] The pathogenicity of the anaerobic Streptococcus depends upon the proper conditions. These two organisms, as the major symbiotic pair, in the presence of suitable damaged tissue, appear to have been the causative agents. It may be that the other organisms played a supporting role or were secondary invaders. Weiss [11] has demonstrated that in a variety of infections harboring the anaerobic nonhemolytic Streptococcus a multiplicity of organisms was present.

Interesting facet of this case was the fact that the patient had been a frequent blood donor prior to the operation. There was no reason to suspect that these multiple bleedings had a deleterious effect on the condition of the peripheral blood; on the contrary, the hemoglobin and red blood count on admission to the hospital were good. Snapper, Liu, Chung, and Yu,[12] in 1939, studied 101 blood donors who had donated from 1 to 25 liters of blood in periods ranging from 2 months to 10 years; the frequency and extent of anemia increased with an increase in the total amount of blood withdrawn or in the duration of the service. In our patient there was no reason to suspect damage to the hemopoietic system as reflected in the peripheral blood. Doan and Cunningham [13] used rabbits experimentally as donors on many occasions. The bone marrow of these animals showed extreme hyperplasia of bone marrow elements, but they also showed small noncellular areas from which the myeloblasts had disappeared. The authors felt that the evidence indicated a secondary anemia of long standing. There were also small acellular areas containing either a hyaline-like structureless, ground substance or fine globules of fat, and abnormal myeloblasts were evident. In our patient the peripheral blood response was adequate, and there was no reason to suspect a faulty bone marrow. It is possible that there was some fault in tissue resistance engendered by the multiple bleeding, which may have, in association with the local trauma resulting from surgical procedure, prepared the bed for the resistant infection that followed.

The anaerobic organisms are generally resistant to the action of chemotherapeutic agents, including both the sulfonamides and penicillin, and this is also true when they are in synergism with other organisms. As with the gangrenous forms of infection,[14] phlegmonous or cellulitis infection should be treated intensively, early, and specifically according to the etiological agents.

SUMMARY

1. A fatal case of postoperative progressive abdominal wall cellulitis is reported.

2. The primary etiological factor appeared to be a synergism between an anaerobic nonhemolytic Streptococcus and a gram-positive hemolytic aerobe of the species Bacillus subtilis.

3. Postoperative progressive synergistic bacterial gangrene and cellulitis are similar in clinical course, etiology, predisposition, resistance to treatment, latent period, general anatomic location, and rarity. They differ greatly, however, in appearance.

4. Bacteriological study of postoperative wound infections, even in this era of advancing antibiotic therapy, is still of importance. The organisms causing such an infection should be determined definitively, and the infection should be eradicated early.

ACCIDENTAL POISONING BY TOXAPHENE

REVIEW OF TOXICOLOGY AND CASE REPORTS

Lemuel C. McGee, M.D., Ph.D., Howard L. Reed, M.D., Wilmington, Del.
and
James P. Fleming, M.D., Hearne, Texas

A recently developed insecticide, which has demonstrated its effectiveness against a variety of agricultural and livestock insect pests, is chlorinated camphene, commonly known as toxaphene. The empirical formula is $C_{10}H_{10}Cl_8$. The technical material is an amber waxy solid with a mild terpene odor. It contains from 67 to 69% chlorine and melts at temperatures of 70 C to 95 C. It is soluble in the common fat solvents and insoluble in water.

Single dose administration of toxaphene to laboratory animals shows a variable toxicity, depending on the physical form of the poison, the concentration, and the vehicle and means of administration. In white rats the oral L. D. 50 for a 1% emulsion in peanut oil and acacia is 40 mg. of toxaphene per kilogram of body weight of the animal.[1] The L. D. 50 in the rat for a 20% kerosene solution is 100 to 150 mg. per kilogram, for a 5% solution in kerosene, 300 to 350 mg., and for a 5% solution in corn oil, 120 to 125 mg. The intravenous L. D. 50 in the rat with a 1% toxaphene emulsion in peanut oil and acacia is approximately 13 mg. per kilogram.[1] In guinea pigs the L. D. 50 by oral administration of 5% toxaphene in kerosene is 350 to 375 mg. per kilogram, and of 5% toxaphene in corn oil, 250 to 280 mg.[1] In the dog, Lackey[2] found that generalized convulsions resulted from doses as low as 10 mg. per kilogram, when a digestible oil was used as a vehicle. The average lethal dose from oral administration in dogs lay somewhere between 15 mg. and 40 mg. per kilogram.

Toxaphene, in a suitable vehicle, can be absorbed through the skin of rabbits. From peanut oil solution on the skin, a dose of 250 mg. per kilogram may kill the rabbit in 24 hours.[1] From kerosene solution, 100 mg. per kilogram applied to the skin daily for six days gives a high mortality rate in the rabbit and guinea pig. By contrast there is poor absorption by the skin of toxaphene mixed in an inert powder. Rabbits require 500 to 1,000 mg. per kilogram of toxaphene, applied in a 40% dust, to give symptoms of poisoning or death in 24 hours. This species is unaffected by daily application to the skin for six weeks of a 5% toxaphene dust at the rate of 125 mg. toxaphene per kilogram.[1]

It has been found that feeding toxaphene at rates of 100 ppm and 800 ppm in the diet of white rats and guinea pigs for a period of six months shows no significant effect on growth, blood cell count, urinalysis, reproduction, mortality, or histological findings.[1] A study of chronic toxicity in the dog has been reported by Lackey.[2]

From these and other unpublished observations on the effects of toxaphene on 10 species of animals, it has been found consistently that the manifestation of poisoning by this insecticide is diffuse stimulation of the cerebrospinal axis resulting in generalized convulsions. Sublethal doses cause shorter and fewer convulsions than do higher doses. If the dose is lethal, death is due to respiratory failure after a series of convulsions of increasing severity.

Barbiturates protect dogs against supralethal doses of toxaphene. After recovery from the barbiturate anesthesia the animals show no abnormal neurological signs suggestive of organic pathology in the central nervous system. Apparently, the effects of the insecticide on the nervous system are drug-like and reversible. The strikingly selective action of toxaphene on the central nervous system can best be explained by its high lipoid solubility. Lackey concluded that the barbiturates were the preferred depressants in protecting dogs against poisoning.

"If convulsions begin before treatment is instituted, sodium pentobarbital seems to be the drug of choice."[3]

During the five years in which chemists have done research on this material and in which scores of workers have been potentially exposed during manufacture of toxaphene there has not been an instance of poisoning in man. Periodic examination of these workers has shown no alteration in reflexes, subjective manifestation of disorders of the nervous system, or other signs of health impairment. Urinalyses and blood cell counts have been normal; furthermore, we have learned of no instances of accidental poisoning among workers exposed in the manufacture of insecticides containing toxaphene. Such exposure to a worker in a well-controlled manufacturing operation would undoubtedly be minimal. In some instances, however, it is known that recommended precautions in manufacturing processes have been ignored. Since several hundred men have been involved in such work it is apparent that the hazard from inhalation and skin absorption by man is actually not great. Such agents as solvents, inert dusts, and chlorine have been more troublesome than toxaphene from the point of view of the worker during manufacturing and compounding.

As with other economic poisons used in agriculture, one may expect that increasing use of toxaphene will be accompanied by instances of human poisoning through accidents and careless misuse of the agent. Physicians will be called on to treat such patients, and it is for this reason that a discussion of the essential pharmacological properties of toxaphene has been presented. Such pharmacology is based on observations made largely in laboratory animals that were poisoned by known doses of technical toxaphene. When the material appears in insecticides, it is diluted or dispersed with dusts, solvents, and water, and may be found mixed with other insecticidal materials. The latter may modify the manifestations of poisoning. The label on finished insecticides should show the presence and quantity of active ingredients.

The following case reports describe instances of death or illness that, in our opinion, were probably due to toxaphene. The poison was taken by mouth in each case. The symptoms were those to be expected from toxic amounts of toxaphene.

REPORT OF CASES

Case 1.—A Negro boy, aged 2 years and 8 months, played in a yard where there were strips of metal from flattened drums from which technical chlorinated camphene (toxaphene) had been removed previously in a processing plant. The metal sheets had been brought from the plant and part of them used that day to cover the walls of a garden tool storage shed. An amber-colored, beeswax-like material, identified as toxaphene, was subsequently found on and readily scraped from the metal sheets. No one saw the child ingest this material, but it was available to him, and he was known to have played in the vicinity of the sheets. The lack of taste and softening of technical toxaphene at body temperature enables one to chew it as readily as paraffin wax. The child left the play yard before 5 p. m. on this particular afternoon, had a bath and ate his supper, and played in his home until bedtime, at 8 p. m. There was no sign of illness until he awoke just after midnight, screaming and in a convulsion. The child was taken to the emergency ward of a hospital at 1 a. m. Here he received an unidentified hypodermic or intramuscular injection but continued to show intermittent convulsions. An hour later an attempt was made to transfer the patient by car to another hospital. He died en route at about 2:30 a. m. during a convulsion. At autopsy it was found that a "pale froth" was exuding from the mouth, the heart was greatly dilated, and the lungs were markedly congested and edematous. The bronchial tree was filled with a faintly blood-tinged froth; there was no foreign material in the respiratory tract. The stomach "was dilated with air." The liver, gallbladder, and spleen were grossly normal. There was much hard fecal material in the rectum. The kidneys were "rather swollen and the hilus of the right kidney showed a purulent-like material, possibly a pyelitis." A few petechial hemorrhages were found in the white substance of the brain. "No old scars of birth injuries were noted." In stating the immediate cause of death the pathologist reported "symptoms and pathological findings are consistent with a death from a central nervous system poison of a convulsant-type. Actual death was due to suffocation during a convulsion."

Case 2.—A 4-year-old white boy is believed to have ingested an unknown quantity of toxaphene emulsion in water from a gallon jug. The child's stomach was probably empty at this time. The first convulsion occurred about two hours later and continued at two to five minute intervals until death. Death occurred about six hours after the time the poison is believed to have been ingested. Intramuscularly administered magnesium sulfate, phenobarbital sodium, and curare and cyclopropane anesthesia were used in treatment at a hospital shortly before death of the patient. Autopsy was not performed.

Case 3.—A 17-month-old white boy played where his father was mixing toxaphene for a tobacco spray. The youngster picked up a tin cup being used in this process and drank at 6 p. m. what his father called "about a half teaspoon of full-strength toxaphene" (an investigator designated this a solution of toxaphene, presumably a 60% concentration in special solvents). After an unspecified interval, convulsive seizures developed in the child, which recurred with increasing frequency until death at 5 a. m. the following morning. There was no autopsy, and no details are available regarding treatment other than that medical care was given within an hour of the ingestion of poison.

Case 4.—A 2-year-old Negro boy is believed to have ingested an unknown amount of toxaphene. The history stated "while his mother was working in the cotton field, the child ingested a large amount of a chemical containing 20% toxaphene." After an undetermined interval, convulsive episodes developed in the child. He was hospitalized within one-half hour of the onset of the convulsions, and the record of physical examination described the child as "a well developed, well nourished colored male infant who exhibits mild cerebral excitement with hypertonicity of all extremities; aimless jerking motions of all extremities, proceeding to generalized convulsions associated with marked pharyngeal and laryngeal spasm and respiratory embarrassment and cyanosis. E.E.N.T.: Pupils are fixed and dilated. Eyes have a wild, staring expression. Otherwise, negative except for enlarged tonsils. Neck stiff, back bowed: Heart and lungs clear to percussion and auscultation. Abdomen: negative except for spasm of the anterior abdominal wall." The child received "large doses of sodium luminal and curare intramuscularly." Artificial respiration with an air way in place was given during the convulsive episodes. He remained in a critical condition for several hours. Twelve hours after admission to the hospital, he was in relatively good condition and recovered with no untoward symptoms. He was discharged two days later.

Two instances have been found of group poisoning believed to be due to toxaphene, following its misuse as an agricultural pesticide. All these patients recovered.

Case 5.—A Negro farmhand sprayed a collard patch twice on Oct. 4, 1951, with an insecticide that contained approximately 9% toxaphene as an aqueous emulsion. On Oct. 7, a Negro woman, aged 49, picked collards from this patch, washed them three times in different water, and cooked the greens for one hour with a piece of salt pork. Her family of seven ate the greens at 5 p. m. (no other meal had been served since breakfast). At about 6:30 p. m. she "got sick at the stomach," vomited, and took 2 oz (60 cc.) of castor oil in vinegar. She thought little of the episode because she "has a lot of gas most of the time." She had no further symptoms.

---

[3] Lackey, R. W., and Weed, O.: Treatment of Acute Toxaphene Poisoning in the Dog, South. M. J. 44:165 (Feb.) 1951.

At 7:30 p. m. a 20-year-old Negro woman fell to the floor in a convulsive seizure lasting 10 minutes. After the convulsion, she became lucid but had no recollection of having fallen or of the convulsion. At 8:15 p. m. she had a second convulsion coincident with her arrival at a hospital. A stomach tube was passed, and the stomach was lavaged with 2 liters of warm sodium bicarbonate solution. Vomiting of "a large amount of collard greens" followed this treatment. At 10 p. m. 2 grains (0.13 gm.) of phenobarbital sodium was given subcutaneously. No further symptoms were observed. At 8 p. m. a Negro girl, aged 12, fell suddenly in a convulsion. This was followed by a lucid period of about 20 minutes' duration and then another convulsion at 8:30 p. m. At the hospital she was given apomorphine hydrochloride, 0.05 grain (3 mg.), by hypodermic and gastric lavage. "An enormous amount of collard greens were evacuated within a short interval." She received 2 grains (0.13 gm.) of phenobarbital sodium subcutaneously that night, ate a good breakfast the following morning, and objected to being kept home from school, since she felt entirely well. A 16-year-old Negro girl had brought the two patients described above to the hospital. She had no evidence of illness until she fell unexpectedly in a convulsion in the hospital corridor. The fit lasted three to four minutes, after which she was quite rational and cooperated in drinking a quart of warm water containing sodium bicarbonate. She was given apomorphine hydrochloride, 0.10 grain (6 mg.), after which she vomited a "copious amount of collard greens." The onset of her convulsion was approximately 3 hours and 45 minutes after eating the greens. She received phenobarbital sodium and had no further convulsions. The following morning there were no complaints or physical findings other than "weakness and lassitude." In the woman who had picked and cooked the greens and in three other members of the family, 30, 10, and 7 years in age, symptoms of poisoning did not develop during medical observation. Four hours after ingesting the greens each of them was given 2 oz. of castor oil. Subsequent examination of members of this family has revealed no evidence of disease. On Oct. 8, an examination of the garden showed that it was badly grown up in weeds and that both weeds and collard greens were severely burned by the spray material. Samples of the collard leaves were forwarded to the experiment station of the Hercules Powder Company for analysis for organic chloride content. The results of the analysis are shown in table 1. An extremely heavy insecticide residue was present on all of the material. Since toxaphene, like other chlorinated toxicants, is not soluble in water, washing in water does not remove significant amounts of the material from vegetation. On the basis of the analyses, one may calculate the amount of toxaphene ingested by assuming quantities of the greens that may have been eaten (table 2).

Case 6.—In the second instance of group poisoning, a white man sprayed his garden chard with an unspecified amount of toxaphene one morning and harvested the same chard leaves for the family meal that evening. The chard was washed before it was cooked. The meal was eaten at 6 p. m. by the man, his wife, and their son. At 10 p. m. the son was awakened from sleep by a "jerking and twisting" in his muscles. He left his bed feeling ill and provoked vomiting by placing his fingers in his pharynx. He was given strong coffee and tea and forced to vomit repeatedly. At 11 p. m. the man found that his "mind went blank with no warning of nausea or any symptom." Within two or three minutes he fell in a "stiffened heap on the floor." The wife and son lifted him to a couch, pried his "locked jaws open," and forced him to vomit. He is reported to have been unconscious for an hour. No mention is made of clonic movements. At an unspecified time his wife noted lightheadedness and a feeling of mild nausea but could vomit only by deliberately provoking it after taking fluids. The patients were not seen by a physician that night. The man reported the episode by letter, which included these statements: "We are fifty miles from a doctor; no help there. The family was extremely weak for several days. Two days after the poisoning I went to a doctor, and he said if I were all right as far as emptying out the digestive tract, there would not be after effects. However, I did have amnesia for about a week. There were many things I did about the ranch that I could not remember having done two weeks later, such as moving machinery and tasks accomplished." He stressed the absence of warning symptoms, nausea, and cramps, and stated that vomiting had to be induced in himself and his family.

Table 1.—*Residual Toxaphene on Collard Greens*

Sample	Description	Organic Chlorine Calculated as Toxaphene, Ppm
1	As picked	3,312
1-A	As picked	3,318
2	Washed 3 times	3,126

Table 2.—*Dose of Toxaphene in Relation to Amount of Collard Greens Ingested*

Weight of Greens		Residual Toxaphene, Mg.	Dose of Toxaphene in Mg./Kg. of Body Weight*
Gm.	Lb.		
200	0.44	663	9.5
500	1.1	1,658	24.0
1,000	2.2	3,315	47.0

* Assuming a body weight of 70 kg. (154 lb.).

These case reports appear to confirm the laboratory findings that toxaphene acts chiefly as a convulsant drug. No clinical picture of chronic poisoning in man has been developed. This is consistent with Lackey's finding[2] that dogs receiving a convulsant dose of toxaphene daily appear alert and behave normally except for the convulsion. Such doses given over long periods can produce in dogs degenerative cellular changes in the liver and kidney. There were no manifestations of poisoning in these cases until the acute overstimulation of the nervous system occurred following absorption of the poison. In human poisoning, in contrast to that sometimes noted in the dog, vomiting apparently must be induced (one possible exception is mentioned above). There is no abdominal cramping or diarrhea to serve as evidence of poisoning.

SUMMARY AND CONCLUSIONS

1. Three deaths in children presumably resulted from accidental ingestion of lethal amounts of an insecticide, toxaphene. A fourth child so poisoned recovered.
2. Two instances of group poisoning, that followed ingestion of toxaphene-sprayed collards and chard, respectively, have come to our attention. Among 10 persons known to have eaten the contaminated greens, in 7 symptoms developed consistent with toxaphene poisoning as seen in laboratory animals.
3. The onset of poisoning characteristically was abrupt and not associated with abdominal pain, involuntary vomiting, or diarrhea. Illness is manifested by a skeletal muscle response to central nervous system stimulation and by loss of consciousness.
4. These instances of poisoning in humans have resulted from accidents or injudicious use of the pesticide.
5. Since similar poisoning may occur in the future, it is essential that physicians recognize the cardinal symptom, a convulsion, and the importance of countering the acute central nervous system stimulation with barbiturates.
6. The complete absence of poisoning in workers who manufacture toxaphene and in those who are exposed to it, both in the compounding of pesticides and its use in agriculture, suggests that it can be handled with safety.
7. This and other effective pesticides are known poisons and must have lethal qualities if there is to be progress in man's war against insects. Such chemicals should be used properly and with precautions against human consumption if tragedies are to be avoided.

Delaware Trust Building (Dr. McGee).

LOW HEMOGLOBIN LEVELS IN WOMEN AS REVEALED BY BLOOD DONOR RECORDS

George W. Hervey, Sc.D., Ross T. McIntire, M.D.
and
Virginia Watson, M.S., Washington, D. C.

In American Red Cross blood procurement records women constitute a minority of the donors represented. The greater response by men can be attributed largely to more intensive recruitment among male employee groups, to less fear of venipuncture, and to more widespread knowledge of the therapeutic uses of blood and its derivatives, gained while serving in the armed forces. Furnishing the stimulus for the present report, still another element of the disparity is the fact that on presenting themselves many more women than men are found to be unacceptable because of low hemoglobin levels.

Previously unpublished information concerning the incidence of low hemoglobin levels can be derived from mass data pertaining to white persons who volunteered to contribute blood in the period January, 1948, to June, 1949, inclusive.[1] All ranged in age from 18 through 59. Shown in table 1 are figures on 239,191 persons (165,408 men and 73,783 women) [2] who volunteered to make their first donations at the regional blood collecting and processing centers or mobile unit operations.

Compared to less than 1% of the men, 12.6% of the women were unable to meet a requirement of 12.3 gm. of hemoglobin per 100 cc. of blood, which was the minimum for acceptance of a person as a blood donor.[3] A copper sulfate technique modified from the method of Phillips and co-workers [4] was employed in all determinations.

During the past two years occasional checks have disclosed a practically unchanged aggregate number of low hemoglobin level disqualifications per 100 women. Assuming that the women who present themselves at the Red Cross centers are above the general average in health, a less satisfactory situation must exist in the nation as a whole. By extending census figures we place the total number of women who range between 18 and 59 years old, inclusive, at approximately 47 million. Risking an insecure estimation, the number of women deficient in hemoglobin and therefore potentially disqualifiable may run from nearly 6 million (calculated from the Red Cross data) to well over 10 mllion. Anemia is bound to engender rising medical interest if the hospital demand for blood should continue to increase, since procurement would be broadened to encompass larger segments of the population, and women would be prevailed on to donate in greater numbers.

TABLE 1.—*Donors and Disqualified Persons in Selected Groups*

	Men	Women
Total no. of persons	165,408	73,783
Number disqualified		
All reasons	13,798	15,233
Low hemoglobin level	1,382	9,322
Percentage disqualified		
All reasons	8.3	20.7
Low hemoglobin level	0.8	12.6

Analytical discussion is now feasible with special reference to a selected group of 6,911 women, included in table 2. All successfully donated blood on first visits and came back within one year to do so again. Thereupon 12.3% were disqualified owing to a low hemoglobin level. On the average the group members were 37.3 years of age at the time of second visits and had waited 5.6 months before returning. From tables 2 and 3 we find that those rejected (1) were relatively more numerous among persons returning from 2 to 10 months than earlier or later, (2) averaged 5 months younger than the women accepted, (3) were relatively more numerous among persons between 21 and 50 years than younger or older, and (4) averaged six days sooner in returning than those accepted.

TABLE 2.—*Distribution of Selected Women According to Interval Between First and Second Visits and Average Ages*

No. of Months Between First and Second Visits	Number			Percentage Disqualified	Average Age (Years)	
	Total	Disqualified	Accepted		Disqualified	Accepted
Under 2	224	13	211	5.8	33.3	33.3
2- 3.9	2,084	278	1,806	13.3	37.1	37.7
4- 5.9	2,041	274	1,767	13.4	37.0	37.8
6- 7.9	1,297	164	1,133	12.6	37.5	37.5
8- 9.9	741	82	659	11.1	35.3	36.9
10-11.9	524	41	483	7.8	36.3	36.0
Total	6,911	852	6,059	12.3	36.9	37.3

Whether the group was considered compositely or divided into subgroups according to the period between the first and second visits to permit views of the net relationships, a characteristic pattern unfolded. Starting with approximately 9.1% of the women 18 years old, the gross low hemoglobin level disqualification curve proceeded upward to a plateau, was above 13.5% from 34.5 to 44.5 years, and then declined to 6.3% by the end of the 59th year. Though differing in magnitude from one subgroup to another, the rejection rates adhered to the general trend no matter how long the interval to the second visit. Incidentally, the variations strengthen the frequently expressed view that women in their fifties, usually poorly represented in blood program records, should be desirable for donor recruitment.

From National Headquarters of the American National Red Cross.

[1] In the period designated, the blood program was composed of nine constituent programs, located in the following regions: Rochester, N. Y.; Wichita, Kan.; Atlanta, Ga.; Washington, D. C.; Los Angeles; St. Louis; Detroit; Columbus, Ohio; and Massachusetts exclusive of Boston.

[2] Based on convenient blocks of machine record cards. The totals in the top line of table 1 do not portray those of a typical division according to sex. Experience shows the following averages: men, 73.6%; women, 26.4%. These proportions applied to the figures on the bottom line of the table yield 3.9%, which represents typical low hemoglobin occurrence among white blood donors in both sexes.

[3] Present minimum, 12.5 gm.

[4] Phillips, R. A., and others: Copper Sulfate Method of Measuring the Specific Gravities of Whole Blood and Plasma, Bull. U. S. Army Med. Dept. (no. 71) pp. 66-83 (Dec.) 1943.

Obviously little meaning could be attached to the observed tendencies if the physicians on duty had subjected persons in the terminal age classes more than others to unusually careful questioning before accepting or rejecting them. Inquiry uncovered no intimation that such selectivity could have affected the reported figures in more than a very minor degree. Consequently, under the conditions specified for the subgroups (number of months between visits constant), the statistical findings seem plausible. Our demonstration that the host of factors governing the disqualifications included factors peculiarly associated with the ages of the women is consistent with published hemoglobin weights. The preponderant evidence in reports by Pett and Ogilvie,[5] the Medical Council of Great Britain,[6] Bryce and Jakobowicz,[7] and Howell[8] would indicate that the values are normally greater in women belonging to the age groups under 20 years and above 50 years than to other groups.

Another age phenomenon came to light in the form of a preliminary period upon the termination of which the determinations of low hemoglobin levels began to be comparatively less numerous. In regard to the women 21 through 59 years, aggregating 80.5% of the entire group, this period averaged 5.8 to 6 months in duration from the dates of the initial blood donations; however, the women 50 years and older were not disqualified in lessening frequency until the stage of nondecline had lasted 7.4 months, whereas for those under 21 years it ended at only 5.2 months. The differences seem to reflect corresponding differences between the older and younger women with respect to the power of their bone marrow to regenerate erythrocytes. (Nothing said here is incompatible with a requirement that at least eight weeks must elapse between donations, and no person shall be accepted more than five times a year.[9])

TABLE 3.—*Distribution of Selected Women According to Age on Second Visit and Average Interval Between First and Second Visits*

Age (Years)	Number			Percentage Disqualified	Average No. of Months Between Visits	
	Total	Disqualified	Accepted		Disqualified	Accepted
Under 21...	265	25	240	9.4	5.2	5.7
21-29.......	1,857	226	1,631	12.2	5.3	5.6
30-39.......	1,932	261	1,671	13.5	5.6	5.7
40-49.......	1,774	242	1,532	13.6	5.3	5.6
50-59.......	1,080	98	982	9.1	5.1	5.4
All ages....	6,911	852	6,059	12.3	5.4	5.6

After the expiration of the preliminary period the disqualification rates diminished in accordance with a lengthening interval to the second visit. The downward trend was noticeable when women of the same age were considered. Hence, the inference is forthcoming that the total causes of low hemoglobin levels embraced factors independent of age but definitely related to the passage of time to second visit. Toward the end of one year from the first visit the action of time influences weakened and relatively more women were then able to meet the prescribed hemoglobin test.

Left for brief mention is a supplementary group of 458 women who presented themselves 12 to 15 months subsequent to first donations. The low hemoglobin level disqualifications suggest that some women, up to 15.9%, psychologically hostile or feeling unequal to second contributions, eventually accede as a matter of civic duty. We know that so far as practicable many chapter recruitment committees seek out previous donors at the end of a year's nonreturn to the regional centers. The limited additional data suffice merely to raise the possibility that self-screening by the less physically able persons complicates the task of persuading previous women donors to maintain their support of the blood program.

SUMMARY

There are now in the United States an estimated 47 million women in the customary age range for blood donors, 18 through 59 years. Of that total, the number subject to being disqualified because of low hemoglobin levels may greatly exceed 6 million. Anemia is bound to be a subject of increasing medical interest if expansion of blood program operations should be continued, broader segments of the population included, and donor recruitment directed more intensely to women than at present. These comments result from a review of mass data collected by the American Red Cross.

Sample data on 239,191 white persons (165,408 men, 73,783 women) show that on their initial visits to donate blood at Red Cross regional centers or mobile unit operations 12.6% of the women (as compared to less than 1% of the men) were unable to meet a minimum requirement of 12.3 gm. of hemoglobin per 100 cc. of blood. A study of the records pertaining to a selected group of 6,911 women who had been successful donors on first visits revealed 12.3% rejected for the same reason on second visits made within a year thereafter. Statistical considerations indicate that the second visit disqualifications were related to the ages of the women, length of interval between the first and second visits, and other, undetermined factors.

The disqualifications were relatively more numerous during the most prevalent ages for child bearing and care and less numerous among younger women and those in their late forties and fifties. They were also fewer toward the end of one year from first visits than sooner; however, only upon the termination of a preliminary period averaging 5.9 months in duration were diminishing low hemoglobin levels in evidence. The exact point in time marking the beginning of the decline differed according to the women's ages, apparently reflecting a corresponding variation in the power of bone marrow to regenerate red cells of the blood.

CLINICAL NOTES

MULTIPLE ANEURYSMS OF THE RIGHT CORONARY ARTERY

DEATH FROM A RUPTURED ANEURYSM OF THE ABDOMINAL AORTA

George J. Rukstinat, M.D., Chicago

REPORT OF A CASE

B. F., a Jesuit priest 67 years of age, was brought by ambulance to the Loretto Hospital on Oct. 26, 1950. He complained of severe abdominal pain, which was most intense in the left lower quadrant. The pain was not relieved by an enema or by 1/6 grain (0.01 gm.) of morphine sulfate given hypodermically. A second similar injection of morphine given three hours later induced a brief fitful sleep. The patient awakened with pain in the abdomen and back and moaned and tossed in agony. He had been in the hospital only six hours in his terminal stage and was thought to have a mesenteric thrombosis.

The blood pressure was 190/110 on several readings and was in marked contrast to his usual pressure of 124/80. The lower pressure had been recorded on numerous occasions in the preceding six years and even while the patient had been hospitalized for coronary insufficiency and myocardial infarction.

The pain in the abdomen was difficult to evaluate, because of a history of so-called colitis. Various episodes of this condition had been self-medicated with cathartics and alkaline powders for many years. An especially severe abdominal pain five days before death had been so treated. This was at a time, in the last two weeks of October, 1950, when the patient had a variety of other symptoms. First hemiparesis occurred and was associated with dysarthria. The conditions developed over several days and resulted only in a minor disability in movement. They had improved to the point where the patient had resumed his duties just prior to his death.

A review of his personal history disclosed "rheumatic trouble" at 6 years of age, but details were lacking. There was hospitalization in 1939 for repair of a ruptured left quadriceps femoris muscle. This was incurred 14 months previously in a baseball game. At this time the heart had a normal rate and rhythm and all laboratory tests showed normal blood and urine.

Despite the good condition of the heart in 1939, the patient had a severe anginal attack in 1940. His condition improved after a 10 day stay in the hospital. The electrocardiogram showed some inversion of the T wave in lead 1. No repetition of the attack occurred for six years, and in the interval the patient resumed his duties as a religious instructor. His pulse was good, and his blood pressure was from 115 to 125 systolic and 70 to 80 diastolic.

In February, 1946, the patient had two attacks of angina pectoris. These were so severe that he recorded their occurrence distinctly at 10 a. m. and 1 p. m. The pain was in the chest at the level of the heart and radiated to each shoulder. Glyceryl trinitrate therapy relieved the pain. The electrocardiogram showed low-voltage QRS complexes, suggesting diffuse myocardial disease. The P-R interval at 0.20 suggested impending first degree auriculoventricular block. The diagnosis on discharge was arteriosclerotic heart disease and angina pectoris without coronary artery occlusion.

No similar episode occurred in the interval between February, 1946, and October, 1950, when the aforementioned abdominal symptoms occurred, and the patient was brought to the hospital for emergency treatment on the service of Dr. Francis Foran.

At autopsy, performed immediately after death, the following observations were made: The abdominal cavity contained 50 cc. of fresh blood from minute tears in the peritoneum near the left kidney. There was hemorrhage beneath the mesosigmoid close to its attachment to the posterior wall, and the blood extended laterally to the outermost edge of the left rectus muscle. The hemorrhage also extended retroperitoneally to the region of the left kidney and downward beneath the covering of the urinary bladder. In the region of the lower pole of the left kidney the hemorrhage extended to the right of the midline, across the duodenum, and into the mesentery for the small bowel for 8 cm.

The left adrenal gland was extensively dissected by hemorrhage, and some parts of the cortex resembled canary yellow islands of tissue in a sea of blood. The first impression was of an adrenal tumor in which a blasting type of hemorrhage had occurred. The origin of this huge extravasation was, however, in a saccular aneurysm of the aorta just proximal to the bifurcation. The aorta was dilated to a circumference of 12 cm. at this point, whereas above the dilation the greatest circumference was 7.2 cm. There was dissection under the lining of the aneurysm in a place 6 cm. in diameter and through an atheromatous patch 8 mm. thick. The splitting of the aortic layers proceeded circumferentially to a rupture through the adventitia and produced the hemorrhage already mentioned. The free blood in the retroperitoneal fat amounted to 1,500 cc. There was, in addition, at least 500 cc. of blood in the aortic wall, in the mesentery for the small bowel, and in the fat close to the left kidney.

The lungs were emphysematous anteriorly and subcrepitant dorsally. There were coal-pigmented nodules with gray fibrous centers, resembling arrested tubercles in the upper lobe and apex of the left lung. There was a similar nodule in the lower lobe of the right lung.

The root of the aorta had its lining altered about 50% by fatty and fibrous patches. This change increased gradually throughout the thoracic and abdominal portions of the aorta, so that at least 85% of the lining was involved at the bifurcation and in the common iliac arteries.

The heart weighed 465 gm. The outer wall of the left ventricle was 27 mm. thick, while that of the right ventricle was 5 mm. In many places 3 mm. of the latter measurement was due to fat. The circumferences of the heart valve rings were as follows: tricuspid 13.2 cm., pulmonic 7.4 cm., mitral 9.6 cm., and aortic 7.8 cm.

The coronary arteries were markedly tortuous, and the lining of the left was altered about 65% by fatty patches. The lumen was 11 mm. in circumference close to the mouth and was irregular but nowhere occluded. The right coronary artery was phenomenally altered. The mouth was 5 mm. in diameter. There were six aneurysms of this artery, all along the main descending branch. The first dilation had a calcified lining and was 8 mm. long and 11 mm. in diameter. It began 18 mm. from the artery mouth. The second aneurysm was centered 25 mm. from the first, was of the same size, and had about two-thirds of its lining covered with a partially organized blood clot. The third aneurysm was pouch-like, 6 mm. in diameter, and involved the outer aspect of the artery and almost all of the lining. With the exception of 10% of the left edge, the lining was covered with a stiff red clot, 1 mm. thick. The next aneurysm began 2 mm. more distally, was 18 mm. across, and had a clot obstructing both its entire lumen and that of the vessel on which it was situated. The clot was rubbery and dark red.

After a sclerotic course of 7 mm., the artery expanded into an aneurysm 2 cm. in diameter. This was filled with gray to pink grumous material, which resembled disintegrated clot with added fatty matter from an opened atheromatous region. After a straight interval of 5 mm., the last aneurysm was discovered. It was 7 mm. in diameter, and its lumen was filled with fresh red blood clots.

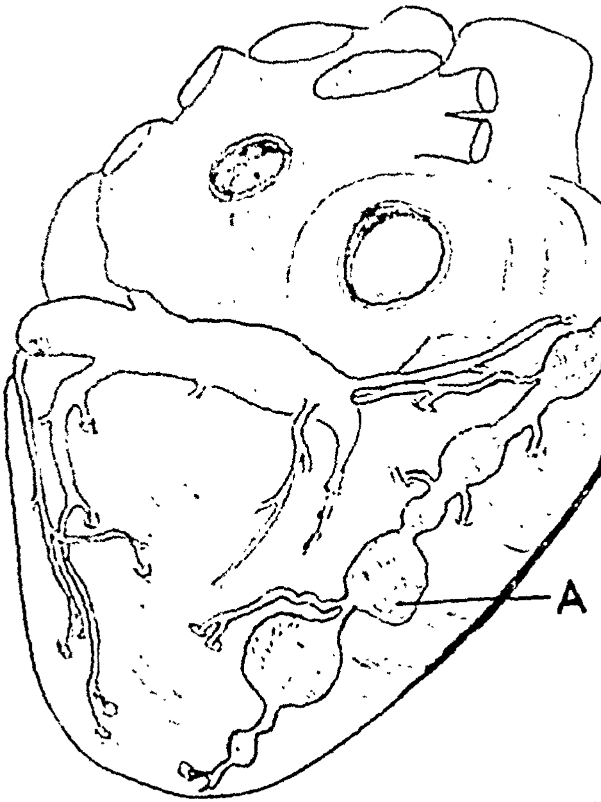
The myocardium of the apex of the left ventricle was scarred in one place 15 mm. in diameter. The lining of the left ventricle on its septal aspect contained eight white scars from 1 to 3 mm. broad and 7 to 12 mm. long. The outer wall of the left ventricle was extensively scarred by white patches from 1 to 5 mm. in diameter, especially in the central third.

From the Department of Pathology, Loretto Hospital, and Loyola University Stritch School of Medicine.

There was also an aneurysmal dilatation, 15 mm. in diameter, of the left common iliac artery 1 cm. distad to its mouth. The wall of the sac was sclerotic and as much as 7 mm. thick. The lining was partially dissected away by blood beneath it in a region 12 mm. in diameter. Here the detached lining was wrinkled. The other organs were remarkably free of changes other than sclerosis of the arteries. The spleen weighed only 75 gm., and its pulp was coarse and nearly bloodless.

Microscopic examination disclosed the following changes: The heart muscle cells showed hypertrophy and had moderate accumulations of polar liopochrome pigmentation. The scar tissue was, in general, old, but occasional sparse lymphocytic infiltrations were seen near the edges of the scars. There were also patches showing imperfect staining and haziness as is found in very early myocardial infarction.

Sections from the aortic aneurysm, whose dissection and rupture caused death, showed partial calcification in the atheromatous patch through which rupture occurred. The media showed the irregular track of dissection from the lining to the surrounding fat.



One (*A*) of six aneurysms of the right coronary artery. The heart is viewed from the back.

The aneurysm of the left common iliac artery showed a clot attached to the lining on its outer aspect. There was fresh hemorrhage into all layers of the artery wall. There was advanced sclerosis with partial calcification of the lining.

Sections of the aneurysms of the right coronary artery showed the changes typical of advanced senile sclerosis. There was extensive hyalinization of the media of the third aneurysm and acicular vacuolation indicative of cholesterol deposition. There was partial calcification of the lining.

The left adrenal gland had abundant hemorrhage into both cortex and medulla and into the surrounding fat. The cortical portions of the gland were dissected away from the capsule by hemorrhage in many places. In other regions there was indentation of the capsule from hemorrhage in the surrounding fat.

The prostate gland was involved in a benign hyperplasia of the left lateral lobe. This contained several well-circumscribed adenomas, in which there was papillary overgrowth of lining cells. There was also a slight interstitial lymphocytic infiltration close to the adenomas.

The anatomic diagnosis summarized the findings as follows: marked generalized senile arteriosclerosis; dissecting aneurysm of the abdominal part of the aorta; extensive hemorrhage into the retroperitoneal fat, urinary bladder wall, left adrenal gland, and mesentery for the small bowel; six aneurysms of the posterior coronary artery (several thrombosed); aneurysm with early dissection and clot formation of the left common iliac artery; benign prostatic hyperplasia; and scars of the knees (repair of quadriceps femoris tendons).

COMMENT

Rupture of an aneurysm of the aorta into the pericardial sac is occasionally recognized clinically. Tamponade of the heart by blood pumped into the pericardial sac causes rapid cardiac failure and death in most patients. The most frequent diagnosis is coronary thrombosis. The more gradual dissection through the wall of the aorta from the arch downward, either by rupture of a saccular aneurysm or by a true dissecting type, results in a perplexing series of symptoms. These are referable to the level of the aortic wall being split and are the result of a combination of factors. Chief among these are the disruption of the layers of the aortic wall by hemorrhage, the tamponing of aortic branches, the irritation of nerves in the vessel walls and involved organs, and ischemia of the organs. Patients so afflicted describe the onset of the sudden chest pain as gripping, pressing, squeezing, or "like a red hot poker" being pushed from the neck down through the chest.

In recent years the recognition of the true condition has led to a proper evaluation of the intense pleuritic pain, for example. This is due to dissection of the aorta by blood, which compresses the intercostal arteries especially in their course through the aortic wall. The intense pain in the various segments of the thorax is referable to the advancing thrust of blood within the layers of the aortic wall.

The speed of disruption is dependent on the blood pressure and on the resistance of the aortic layers primarily. The process may be temporarily halted if shock occurs; then the intramural blood may lose its driving force and clot. With the resumption of adequate pressure, the dissection may continue and encroach on any of the aortic branches. In this manner symptoms may occur that are ascribed to all the organ systems.

Death may not result from the first episode of dissection if it is slight. Again the patient's life may be spared if the column of intramural blood breaks through an atheromatous patch at one level in the aorta and, after a considerable distance, reestablishes contact with the aortic lumen. This condition may persist until a smoothly lined channel is formed in the aortic wall.

Dissection of this sort is not infrequent in saccular aneurysms of the abdominal aorta. Such was the condition in the case here reported. The bulging sac of the aneurysm was filled with a laminated thrombus in which there was extensive organization. Rupture of the aorta occurred in an atheromatous patch at the uppermost edge of the aneurysm. From this point the course was similar to that in a dissecting aneurysm, and death occurred in six hours.

The advanced sclerosis of the aortic branches was seen in the iliac arteries. On the left side this patient had a

aneurysm in the common iliac artery 15 mm. in diameter. There was recent hemorrhage beneath the lining where dissection by blood had extended from the abdominal part of the aorta. Such aneurysms in themselves may lead to death.[1] In this patient it might have furnished the point of reentrance of blood into the vascular stream if death had not occurred so rapidly.

In addition to the aneurysms of the aorta and left common iliac artery, this patient had six aneurysms of the right coronary artery (see the accompanying figure). Their location on this artery and the condition of their lumens has already been detailed. Such aneurysms have been the subject of intensive study because of their rarity, their disputed causation, and their failure to produce typical symptoms.

Efforts by roentgenologists to demonstrate sclerotic cardiac coronary arteries in patients have been successful on numerous occasions. In 1927, Lenk[2] demonstrated calcified coronary arteries in the living by using the Potter-Bucky diaphragm. This was followed, in 1934, by a similar study by Wosika and Sosman.[3] They were able to show calcified coronary arteries in three patients. One of these subsequently was examined post mortem, so the clinical findings could be corroborated. More recently not only calcified coronary arteries but sclerotic changes in the heart valve rings have been reported by Koiransky and Ettman.[4] They also had corroboration of their findings at necropsy. Eventually coronary artery aneurysms may be found by such methods. In an article including a splendid review of the literature on coronary aneurysms, Scott[5] reported a globular shadow on the right heart border seen roentgenographically in his patient. At fluoroscopic examinations the shadow was seen to pulsate, and a diagnosis of probable aneurysm of the right auricle was made.

Scott made an exhaustive review and found 47 reported cases of coronary aneurysms since 1812. He classified these as diffuse and localized. The diffuse type apparently is on a congenital basis according to Harris,[6] Forbus,[7] and Rigdon and Vandergriff.[8] They develop in association with defects in the elastic lamella and muscular coats either at a branch or a bifurcation. The condition is similar to the changes noted in congenital aneurysms of the cerebral arteries.

The localized types have been divided as follows: congenital, 15; mycotic embolic, 12; syphilitic, 6; arteriosclerotic, 6; other types, 4; and unclassified, 4. In the 47 cases in which there was a localized aneurysm, the exact site was not specified in three. In the remaining 44, only the left coronary was involved in 27, and only the right in 11; there was involvement of both in six. Thirty-six bodies had single and eight had multiple aneurysms. In the group with congenital aneurysms, there were 14 male subjects and one female, ranging in age from 5 to 84 years. In the arteriosclerotic patients, four were men and one a woman. This group was from 58 to 77 years old. The mycotic-embolic group included six male and four female subjects, from 11 to 45 years of age. There were two additional cases in this group, but the sex was not stated. In the group with this type of aneurysm and the syphilitic variety there were 60% males, in marked contrast with the congenital variety, where males constituted 92.4% of the total.

The variety of alterations in this relatively small group of cases is fascinating. Prior to 1929, the most frequently reported cause of death from coronary aneurysm was rupture. Since that time coronary artery thrombosis and its sequelae have been most common. Not all patients died in a rapid or dramatic manner, however. Although three in the total series had chronic congestive heart failure, the general rule has been for these patients to present no symptoms referable to the heart.

The outstanding example of this fact was presented by Scott.[5] His patient, a man 84 years of age, died of carcinoma of the prostate gland and an ascending urinary infection. At autopsy his heart weighed 780 gm. There were 17 saccular aneurysms in an anomalous coronary artery circulation. The largest aneursysm was 10 by 8 by 8 cm. and was situated near the right auricle. This patient had an abnormal direct connection between the left coronary artery and an accessory right coronary artery. The vessel thus formed connected with the pulmonary artery. A person living to the age of 84 years with such a grotesque coronary circulation may serve as a natural experiment in altered blood flow to the heart. Venturesome surgeons are already furnishing new sources of blood supply to the heart by connecting a systemic artery to the coronary sinus.

Although the aneurysms of the coronary arteries usually produce no specific symptoms, many eventually cause death. Rarely does an aneurysm elsewhere in the body rupture and cause death in a patient who also has an aneurysm of a cardiac coronary artery. There is only one such case reported to date, by Manohar.[9] My case, as far as can be ascertained, is the second to be reported. The patient had six aneurysms of the right coronary artery, an aneurysm of the left common iliac artery, and a huge abdominal aortic aneurysm. The combination is unique for cases of the arteriosclerotic type of aneurysm.

SUMMARY

The literature on aneurysms of the cardiac coronary arteries is reviewed, and pertinent articles are cited. The clinical history and postmortem findings are reported in a case of multiple coronary aneurysms; the patient died of rupture, with dissection, of an arteriosclerotic aortic abdominal aneurysm.

HEMOBILIA, CHOLECYSTITIS, AND GASTROINTESTINAL BLEEDING WITH RUPTURE OF LIVER

Harry J. Epstein, M.D.
and
Benjamin Lipshutz, M.D., Philadelphia

Subcutaneous rupture of the liver is not a rarity. Our case is of particular interest on account of the complications of hemobilia, hemorrhagic cholecystitis, gastrointestinal bleeding, hemothorax, and hydropneumopericardium, with complete recovery. The over-all mortality from hepatic rupture in general remains about 60%, that from massive rupture being higher (60% to 80%).[1]

REPORT OF A CASE

R. G., 9 years of age, a white male child, sustained a severe injury to the abdomen and lower right portion of the chest at 5 p. m. on Feb. 9, 1951, when he fell from his sled into a jagged rock-filled creek. He was brought into the office 20 minutes later in a state of collapse. Shock therapy was immediately carried out with favorable response. X-rays were taken of the abdomen to determine the presence of air under the diaphragm and because of possible fracture of the ribs. The x-rays were all normal. His pulse rate was very slow (40 per minute). He moaned and complained of severe pain in the lower right part of the chest and right upper quadrant of the abdomen. Two central upper incisors were broken transversely in half. The diaphragm did not move with respiration, and there was a large ecchymotic area over the right upper abdominal quadrant. The abdomen was fixed, and peristalsis was not audible. A careful search of the head and spine did not reveal any evidence of trauma. Results of neurological examination disclosed no abnormalities; the eye grounds were normal. While the patient had reacted from the initial shock, the results of clinical survey and the severity of the trauma strongly suggested the possibility that a visceral injury and internal hemorrhage had occurred. The patient was thereupon transferred to the Mount Sinai Hospital.

Physical examination at the hospital revealed a rapid and feeble pulse, subnormal temperature, and cold clammy skin. Blood pressure was 80/30, and respirations were 30 per minute. The right side of the chest was fixed. The muscles of the right upper quadrant of the abdomen showed increased muscle resistance and absent reflexes.

The impression on admission was hemoperitoneum, probably due to a ruptured liver or spleen, with secondary shock and internal hemorrhage. He was given a transfusion of whole blood immediately, then glucose intravenously, a procaine penicillin G preparation (crysticillin®), vitamin K, and other vitamins. The blood cell count showed 62% hemoglobin (9 gm.), 20,850 white blood cells, and 33% hematocrit. The clinical evidence of hemorrhage clearly indicated the necessity of urgent surgery in an effort to locate the source of the bleeding.

Under general anesthesia, an upper right transverse abdominal incision transecting the right rectus sheath and muscle was used to open the abdomen. The peritoneal cavity was filled with bright red blood and clots, after the removal of which a thorough abdominal exploration disclosed a deep laceration of the posterior-inferior aspect of the right lobe of the liver, lateral and posterior to the gallbladder fossa and inferior vena cava. The hepatic area was sutured with surgical gut. The omentum was placed over and in the traumatized hepatic surface, being utilized as a cushion for the sutures. (Omentum acts as a valuable hemostatic and agglutinizing agent and must be sutured to the area of rupture.) Three pieces of gelfoam® (absorbable sponge) were also applied to the sutured site to further control hepatic bleeding. With the bleeding apparently controlled and the visceral injury repaired, the abdomen was closed in layers. The patient left the operating room in fair condition. He was given 750 cc. of whole blood and 250 cc. of 5% glucose by venoclysis during the operation.

On the first postoperative day, the abdomen was softer but peristalsis was still absent. A Levine tube was inserted to control vomiting and reduce gastric distention. Continuous Wangensteen suction was maintained. On the third postoperative day, fluid was found in the right pleural cavity. Hemoglobin was 73%. A transfusion of 250 cc. of whole blood was given. The temperature was sustained at 102 F. Tenderness at the site of his "cut down" in the ankle suggested the possibility of thrombophlebitis. He was treated with antibiotics, oxygen, and fluids given parenterally. X-ray studies showed that the right side of the diaphragm was fixed. It was difficult to determine at this time whether the fixed position of the diaphragm was the result of fluid in the pleural cavity or the beginning of a subphrenic collection. His fluid and electrolyte balance were maintained within normal limits.

On the sixth postoperative day, aspiration of the right pleural cavity yielded 450 cc. of brownish, bloody fluid. The aspirated pleural fluid showed xanthochromia. The right side of the diaphragm continued to be elevated. Persistent physical findings of fluid in the right pleural cavity required repeated aspirations.

Two weeks postoperatively, sharp pain developed in the right upper quadrant of the abdomen radiating to the right shoulder. Concomitant with the pain, vomiting of about 100 cc. of bright red blood and blood clots occurred. Blood pressure was 130/90 and pulse rate 96 per minute. Scleral jaundice and dark urine were evident. A gastrointestinal x-ray was normal.

The next day, the jaundice increased in intensity. The patient again vomited bright red blood and passed a tarry stool. Hemoglobin was 73%. The clinical picture suggested the presence of an acute duodenal ulcer resulting from the initial trauma. An ulcer regimen was instituted, with no subsequent clinical improvement. The pain in the right upper quadrant of the abdomen and hematemesis continued. The hemoglobin dropped to 60%. Frequent transfusions were given but to no avail. The development of a mass in the right upper abdominal quadrant and the patient's failure to respond to treatment prompted the decision to explore the abdomen again.

Accordingly, the patient was operated on 19 days after the first operation. Under general anesthesia, the abdomen was opened through the previous transverse incision. The abdominal cavity was dry, with no gross evidence of bleeding. The gallbladder was found to be acutely inflamed, distended to about six to eight times its normal size, and showed massive, diffuse mural edema. Insertion of a trochar into the gallbladder yielded thick blood clots and bile. A cholecystostomy was performed and a heavy rubber catheter inserted through the trochar opening in the gallbladder. Drainage continued satisfactorily from the cholecystostomy opening. Clinical improvement was immediately evident and continued to complete recovery. The drain from the gallbladder was removed after seven days. Several chest taps were performed, with the removal of slightly blood-tinged fluid. An x-ray of the chest six days after the second operation showed the presence of a small hydropneumopericardium on the right side at the level of the eighth dorsal segment. Since it did not cause any symptoms, it was allowed to absorb spontaneously.

The patient was discharged on March 10 (29 days after admission and 10 days after his second operation), in good condition. Follow-up x-rays two weeks after his discharge from the hospital revealed disappearance and absorption of the chest fluid.

The patient was last seen in January, 1952. He was healthy and active. Liver function tests showed normal hepatic function. A cholecystogram showed normal gallbladder function.

COMMENT

The interesting phases of this case were the occurrence of hemobilia, hemorrhagic cholecystitis, and gastrointestinal bleeding as complications of a ruptured liver. Hemobilia is a term suggested by Sandblom[2] to describe the symptom of bleeding into the biliary tree due to

---

From the Mount Sinai Hospital.

Dr. T. H. Mendell assisted in the management of the patient described.

[1] Sanders, G. B.; Macguire, C. H., and Moore, R. H., Jr.: Massive Rupture of Liver, Am. J. Surg. 78: 699 (Nov.) 1949.

[2] Sandblom, P.: Hemorrhage into the Biliary Tract Following Trauma: "Traumatic Hemobilia," Surgery 24: 571 (Sept.) 1948.

trauma. His investigations reveal that this condition is rare. He described a 7-year-old boy who was hurt by the handlebar of a bicycle and who was operated on 10 days after the injury. A cholecystostomy with drainage was carried out for a distended gallbladder, the contents of the latter revealing bile mixed with blood. Opening of the gallbladder disclosed no definite bleeding site.

Siegel[3] (quoted by Sandblom) described a 32-year-old man who had sustained a blow from the handlebar of a bicycle. Several ribs on the right side were fractured, and bleeding into the right pleural cavity occurred. On the 10th day, the patient passed a blood clot via the bowel and felt better. On the 14th day he was operated on and a large distended gallbladder was found. There were several ruptures in the liver, varying up to 4 cm. in length. A spotty gangrenous gallbladder was removed and the gallbladder bed drained. Postoperatively there was considerable sanguineous drainage followed by the development of icterus. These were attributed to blood clots in the common duct. The patient gradually recovered without further complications.

Sandblom interpreted this case as one of hemobilia, the result of a central rupture of the liver, with the blood carried to the gallbladder through the biliary passages. He collected nine additional cases in which the source of the bleeding was attributed to probable rupture of the central portion of the liver.

Central rupture of the liver beginning in the center of the liver and extending to its periphery usually results from a compression type of trauma. Extension of a central hepatic rupture to or near the portal fissure may readily establish a communication between the vascular tree and one of the larger hepatic ducts. Thus, blood gains entrance into the duodenum and produces hematemesis and melena. The great danger of hepatic rupture is bleeding, particularly from the portal vein branches. The veins of the liver have little supporting tissue and do not tend to collapse. When mixed with bile, the blood shows little tendency to clot.

One cannot exclude the possibility that in our case the initial trauma of the liver was greater than suspected. The injury probably extended toward the portal fissure, where it communicated with the larger biliary ducts. It is conceivable that some of the blood could have drained through the hepatic duct into the cystic duct and remained in the gallbladder. The continued slow bleeding into the biliary tract was clinically masked by the numerous transfusions of whole blood. Two or more weeks elapsed before symptoms referable to this bleeding manifested themselves. By that time, the gallbladder was considerably distended, its walls thickened not unlike those observed in a cystic duct obstruction. The acute onset of jaundice is explained by the sudden blocking of the common duct by a blood clot or bile plug. The rapid disappearance of the jaundice suggests the clot was pushed into the duodenum, thereby opening the avenue for the normal escape of bile.

In further support of the concept that multiple hemorrhages through the biliary tract may stem from a central rupture of the liver is the case reported by Hawthorne and co-workers.[4] In this instance, the hemorrhage through the biliary tract was due to a cavity and a hematoma deep in the liver that continued to necrose and bleed through a large biliary duct until healing of the hepatic rupture occurred.

Additionally, our patient exhibited jaundice while his mother was recuperating from a severe form of infectious hepatitis. The child had last kissed his mother two months previously, when she was first admitted to the same hospital with a diagnosis of infectious hepatitis. The incubation period was well in line with the possible development of this disease in the child. However, subsequent liver function tests suggested an obstructive rather than hepatocellular jaundice.

SUMMARY

A case of ruptured liver complicated by hemobilia, traumatic hemorrhagic cholecystitis, gastrointestinal hemorrhage, hemothorax, and pneumohydropericardium with subsequent complete recovery is reported.

INTUSSUSCEPTION OF THE VERMIFORM APPENDIX

REPORT OF A CASE

David B. Allman, M.D.
Milton Ackerman, M.D.
and
Harry S. Hoffman, M.D., Atlantic City

The first report in the literature on intussusception of the appendix was made by McKidd,[1] in 1858. His young patient died one month after he was first seen, without benefit of surgical treatment. The tremendous strides in surgery since then have established successful therapeutic measures, but preoperative diagnosis has lagged far behind. Rarely has a correct preoperative diagnosis been arrived at, although certain characteristics of the disease are definite enough to warrant its inclusion in the differential diagnosis of surgical disease of the abdomen.

The case reported here is of interest because of the type of intussusception; an invagination of the appendix into itself is rare, and only three previous cases have been reported. The fourth case of this type is reported with a brief discussion of the possible causative factors and a review of the literature.

REPORT OF A CASE

The patient, a 65-year-old white man, was admitted to Atlantic City Hospital June 30, 1951. He was first seen that morning, complaining of severe, cramp-like, intermittent pains in the lower right quadrant of the abdomen, lasting one to three minutes and recurring at intervals of one to two minutes. These had been present for 24 hours prior to admission to the hospital. There was no vomiting associated with the pain, although self-induced vomiting relieved the pain. These attacks had been

similar and recurrent since 1949. At the insistence of his wife, he permitted a physician to see him, and immediate hospitalization was advised. Past history revealed that, in 1937, after sigmoidoscopy, an adenomatous polyp of the sigmoid colon was found and removed. There was no evidence of recurrence following this operation. In January, 1951, he consulted a gastroenterologist about abdominal, cramp-like pains of about two years' duration. There had been some slight weight loss. His general history, otherwise, was not remarkable. Physical examination failed to reveal any palpable portion of the colon. No masses could be felt. There was some slight increase in tympany throughout the abdomen, with occasional hyperperistaltic sounds. Results of rectal examination were negative. Sigmoidoscopic examination, for full distance of the 10-in. scope, disclosed only internal hemorrhoids. Examination with a barium enema showed only a spastic colon. Laboratory studies in January, 1951, showed a normal stool, blood cell count, blood sugar, and blood urea nitrogen and a negative Wassermann reaction.

The patient was pale and thin and did not appear ill. His pulse rate was 96, respirations 20, and temperature 99 F. His tongue and skin were dry. His abdominal wall showed no scars. There was slight distention. A sense of resistance was felt over the entire right side of the abdomen, most marked in the lateral area. No palpable masses were present, and the liver and spleen could not be felt. There was a definite area of tenderness pointing to the right costovertebral area. Results of rectal examination were negative.

Laboratory Data.—There were 16,200 white cells, with 60% segmented and 22% nonsegmented polymorphonuclear cells and 18% lymphocytes. The erythrocyte sedimentation rate was 30 mm. per hour. The blood urea nitrogen was 15 mg. per 100 cc. The urine contained acetone (2+) and a faint trace of albumin.

Course.—A preoperative diagnosis of acute suppurative appendicitis was made, and surgical procedures were instituted. With thiopental sodium anesthesia, laparotomy was performed, through a right rectus incision by one of us (D. B. A.). There was free fluid in the abdomen. The appendix was greatly thickened and shortened and appeared to be intussuscepted. The intussusception was not reduced, but the base was ligated and the appendix was removed by the retrograde method. Ten grams of a sulfonamide preparation was introduced into the abdominal cavity. Two Penrose drains were inserted and the abdomen closed.

Pathological Data.—The appendix measured 3.5 cm. in length and 2.5 cm. in its average diameter. The serosa was covered by a patchy, purulent exudate, and there were tabs of ragged, fibrous connective tissue adhering to it. The distal third was the intussusceptum and completely plugged the lumen of the middle third, or intussuscipiens. The wall of the proximal third was thickened; the mucosa of this portion was congested and its lumen narrowed. The intussuscipiens could be opened for only a short distance beyond the tip of the intussusceptum, beyond which point the two were fused. A cross section, distal to this point, showed a double-barreled structure with marked fibrous thickening of both walls.

Microscopic Examination.—A section of the appendix showed a double-barreled organ. The outer wall had an inner lining of flattened, congested mucosa. The submucosa and muscularis of this wall were broadened by a hyalinizing fibrosis and showed a light infiltrate of lymphocytes and a few polys. In the subserosa, there was capillary engorgement and a moderate polymorphonuclear infiltrate; a thin, fibrinopurulent exudate adhered to the serosa. The intussusceptum, occupying the lumen of this structure, showed a compressed mucosa and a hyalinizing fibrosis of the submucosa and muscularis with a sprinkling of lymphocytes and monocytes in the muscularis and subserosa.

Diagnosis.—The diagnosis was focal acute suppurative appendicitis due to intussusception of the vermiform appendix.

Postoperative Course.—The patient's course following operation was uneventful, and he was discharged from the hospital on the eighth postoperative day.

COMMENT

Less than 100 cases of intussusception of the appendix have been recorded in the literature since the first report of this condition was made by McKidd.[1] In 1941, McSwain [2] conducted a complete and thorough analysis of 77 cases and found the average age of the patients to be about 16 years; the youngest was 13 months, and the oldest was 75 years. He pointed out that the time lag between onset of symptoms and operation ranged from two hours to nine years.

Three types of intussusception of the appendix have been described by Szenes [3]: (1) invagination of the appendix into itself, (2) partial or complete invagination of the appendix into the cecum, and (3) compound intussusception wherein the intussuscepted appendix progresses distally into the colon, including the ileum. Of the total of 82 cases reviewed by Fraser,[4] the first type was present in 2 cases, the second in 44 cases, and the third in 32 cases. The remaining four cases were of intussusception of inverted appendiceal stumps.

The first case of invagination of the appendix into itself was published by Whitrow,[5] in 1930. The patient was a 12-year-old boy who was admitted to the hospital with a history typical of acute appendicitis of 18 hours' duration. At operation, the appendix was found to be the site of intussusception, the tip having invaginated itself until it lay at the base of the appendix. An appendectomy was performed, and the patient's recovery was uneventful.

The second case of intussusception of this type was reported by Fraser,[4] in 1943. His patient was a 75-year-old woman who had both intussusception of the appendix and carcinoma of the cecum. In this instance, the appendiceal intussusception was at the base of the appendix, where the walls were telescoped on themselves for ½ in. (1.3 cm.). The patient's symptoms were referable to the cancer of the large bowel, and the intussusception was observed incidentally.

The third case was reported in 1945 by Ingersoll and Meigs.[6] Their patient was a 45-year-old woman who had intussusception of the appendix with associated endometriosis in that organ.

The mortality rate found by McSwain [2] for intussusception of the compound type was 14.8%, while that of simple intussusception of the appendix was only 2.6%. In the compound type, the intussusception of the appendix will be masked and will not be apparent until the compound intussusception is reduced at operation or it will be discovered postoperatively when the resected specimen is examined. The extent to which the intussusception has progressed will depend on the length of time it has been allowed to persist.

Causation.—Many theories have been presented to explain the development of intussusception of the appendix. Wakley [7] suggested that hyperactive peristalsis

provoked by intestinal parasites or fecaliths may be responsible in some cases. He suggested, too, that the increased lymphoid tissue in the terminal ileum and appendix in young children acts as a foreign body and gives rise to increased and irregular peristalsis of bowel and appendix, which sometimes culminates in intussusception. MacDermott[8] conducted anatomic studies of the base of the appendix and found there a muscular sphincter. He thought the spasm of this sphincter would give rise to a hard mass at the base of the appendix, which would act as the apex of an intussusception. Fraser[4] found the cause of intussusception to be an inversion of the appendiceal stump in 4 patients in whom the appendix had been removed. McSwain,[2] likewise, noted this possibility and brought up for consideration the advisability of invaginating the stump of the appendix after an appendectomy. Ingersoll and Meigs[6] noted that the appendix is capable of rhythmic peristaltic contractions. These contractions, on encountering an area of inflammation within the wall of the appendix or an adherent concretion, result in a buckling inward of the mucosa, followed by the muscularis and serosa with the development of intussusception. If the base of the appendix is constricted and a foreign body or fecalith becomes impacted, the forceful peristaltic action of the appendix may carry that organ into the cecum. Previous inflammatory processes, such as acute appendicitis, may, therefore, set the stage for intussusception.

Symptoms.—McSwain[2] summarized the salient clinical manifestations of intussusception of the appendix as follows: The pain was generally intermittent, cramp-like, and paroxysmal, with complete relief at intervals. Nausea and vomiting almost universally accompanied the pain in 77 patients. Seventeen had blood in the stools. In the majority of patients, the bowels moved normally. There was only slight fever and slight increase in pulse rate or leukocyte count, except in patients in whom necrosis, gangrene, or peritonitis occurred. Distention occurred infrequently, and a mass was noted in 43 patients. There was little muscle spasm, and tenderness was not extreme.

The differentiation of acute appendicitis from intussusception of the appendix, unaccompanied by ileocolic intussusception, is difficult. McSwain[2] suggested the following points to aid in the differential diagnosis: (1) a history of more attacks than are usually seen in acute appendicitis; (2) more definitely cramp-like pains, similar to those of early intestinal obstruction; (3) a history of blood or mucus or both in stools, or their discovery on examination; (4) a history of palpation of a mass in the right lower abdominal quadrant; (5) less fever, increase in pulse rate, and leukocytosis than would be expected in a patient with an appendix inflamed enough to cause a clinical picture of equal severity.

SUMMARY

A case of invagination of the appendix into itself in a 65-year-old man is reported. Intussusception of the appendix into itself is rare, and only three cases have been reported previously. A review of the literature is included in the report.

COUNCIL ON PHARMACY AND CHEMISTRY

REPORT TO THE COUNCIL

The Council has authorized publication of the following report from the Committee on Pesticides, a standing committee of the Council on Pharmacy and Chemistry.

R. T. Stormont, M.D., *Secretary.*

The following article is the fourth in a series of reports concerning pesticides of immediate medical interest. The Committee wishes to acknowledge the assistance of Drs. Robert W. Lackey and Joseph F. Treon, who reviewed the manuscript.

Bernard E. Conley, *Secretary*
Committee on Pesticides

PHARMACOLOGIC PROPERTIES OF TOXAPHENE, A CHLORINATED HYDROCARBON INSECTICIDE

Toxaphene is the accepted common name for a polychlor bicyclic terpene with insecticidal properties. It may be more properly identified as a chlorinated camphene with the average empirical formula $C_{10}H_{10}Cl_8$. The structural formula has not been definitely established since the chlorination of camphene may involve the addition or substitution of chlorine, a rearrangement of the molecule, or a combination of these reactions.

The technical or insecticidal grade is an amber-colored, waxy solid with a mild pine-like odor. It contains 67 to 69% chlorine and melts in the range 70 to 95 C. Although insoluble in water, toxaphene is readily soluble in inexpensive commercial solvents, especially those of an aromatic hydrocarbon nature. It is practically nonvolatile and has residual properties resembling those of DDT (dichloro-diphenyl-trichloro-ethane). Like other chlorinated hydrocarbons of this type, toxaphene slowly evolves hydrochloric acid when heated, the rate depending upon temperature and the presence of catalytic impurities, such as iron compounds. Strong alkalies and ultraviolet light cause a similar breakdown.

The insecticidal effectiveness of toxaphene is caused by combined contact and stomach poison effects. It is a relatively slow acting residual insecticide which is formulated for use as a dust, emulsion, spray, or wettable powder, and incorporated into bait for grasshopper control. Because of its slow action, paralytic agents such as iso-bornyl thiocyanoacetate are used in contact sprays to assure a rapid knockdown of insects. Toxaphene has been used extensively against cotton insects and for the control of grasshopper infestations. It also has been used as a supplement to, and substitute for, DDT for the control of insects resistant to DDT. Toxaphene sprays are not considered to be safe for household application, nor have acceptable medicinal uses for toxaphene been discovered. At one time it was believed to be comparable to DDT as a louse powder because of its persistence and resistance to laundering. Uncertainty as to its cutaneous toxicity in powder form precludes its use for this purpose. In medical entomology, however, it is proving to be a valuable agent for the control of the ticks and mites which transmit disease.

PHARMACOLOGY

Toxaphene is a general convulsant which acts on the central nervous system. It causes diffuse stimulation of the brain and spinal cord resulting in generalized convulsions of a tetanoid or clonic character. In this respect, it acts somewhat the same as DDT and certain other chlorinated hydrocarbon insecticides. Since toxaphene is a chlorinated camphene, it is suspected to have the medullary excitant effects of camphor. Such effects have been observed in several species of laboratory animals.

The occurrence of salivation, vomiting, and reflex excitability to sound suggests a generalized stimulation of medullary centers.

Stimulation of the vasomotor center, evidenced by the abrupt rise in blood pressure in the presence of complete muscular paralysis, occurs in curarized animals following intravenous doses of the compound. There are, however, no significant changes in mean arterial blood pressure following oral administration of toxaphene. This difference in response is probably accounted for on the basis of incomplete absorption of the toxicant from the gastrointestinal tract. The generalized epileptiform spasms which terminate in respiratory failure are also characteristic of a camphor-like compound.

Toxaphene apparently is absorbed irregularly, as a consistent range of toxicity has not been noted in experimental animals. Absorption occurs from the alimentary tract, respiratory tract, or skin, and is partially influenced by the physical state of the technical product. In solution, toxaphene is readily taken up; in the solid form, it is absorbed in toxic amounts depending on the species of animal and the concentration of the powder (dust) used. For example, cutaneous exposure to the 40% technical dust proved to be lethal for rabbits, although higher concentrations applied to the skin of dogs were well tolerated.

Little is known about the distribution, storage, detoxification, and excretion of the compound. The lack of suitable microanalytical chemical methods for the positive identification of minute quantities of toxaphene in tissues or body fluids prevents an accurate determination of its metabolic fate. The high lipoid solubility possessed by this substance suggests that it is probably distributed throughout the various fat depots of the body. Determination of the chlorine content of brain tissue from chronically poisoned dogs indicated storage of the compound as a chlorinated derivative, although the organic chloride content of body fat was not significantly altered. With steers which had been similarly exposed, however, the amount stored in fat tissue was one to three times the amount ingested over a given period.

Toxaphene is believed to be slowly detoxified in the liver. This assumption is based on two observed characteristics; namely, its close chemical relationship to camphor, which is known to be detoxified in the liver, and the isolation of ethereal sulfate and glucuronic acid conjugates of toxaphene in the urine. Toxaphene is also excreted in milk.

TOXICOLOGY

Toxaphene has an irregular toxicity range which basically is due to the vagaries of the absorptive mechanisms in the various animal species. It is toxic by inhalation, ingestion, or skin contact in all forms, but the route of administration and the form in which it is available materially alter the degree of toxicity.

Wide variation in susceptibility has been noted among animals of the same species as well as among those of different species. Dogs are the least tolerant mammals to orally administered toxaphene, followed in an increasing order of resistance by cats, rabbits, rats, guinea pigs, and the larger domesticated animals. This pattern of susceptibility generally is similar to that of most chlorinated hydrocarbon insecticides with two exceptions. Birds, as a group, are not resistant to the compound, having a toxicity range comparable to that for the smaller laboratory animals (50 to 200 mg. per kg. of body weight). Conversely, toxaphene is much more toxic to fish than most other compounds in its class. In this respect it is as toxic as, or more toxic than, rotenone. For this reason, it has been suggested as a useful substitute for the plant insecticide in fish-management work.

The oral toxicity of toxaphene places it among the more toxic of the commercially available chlorinated hydrocarbon insecticides which are acutely poisonous by this route of administration. The oral $L.D._{50}$ ranges from 15 to 375 mg. per kg. of body weight depending on the species of animal and formulation employed, while the intravenous $L.D._{50}$ lies between 10 and 15 mg. per kg. of body weight. This wide variation is believed to be indicative of the irregularities in intestinal absorption which may be expected among most animal species. Since a similar variation among animals exists with orally administered DDT, estimations indicating that toxaphene is approximately four times as acutely toxic as DDT are valid. The fatal dose for man has been estimated to be 2 to 7 gm. Three human fatalities and eight cases of nonfatal poisoning from the accidental ingestion of toxaphene preparations and residual amounts of the technical material alone and on edible crops are reported elsewhere in this issue of THE JOURNAL (see page 1124).

The chronic toxicity of toxaphene for rats is less than that of DDT, being closer to that of lindane. Dogs are particularly susceptible to small amounts of toxaphene given repeatedly over long periods of time, while other animals similarly exposed appear to have a somewhat greater tolerance, especially in the lower dosage ranges. Gross injurious effects, such as retardation of growth, greater incidence of mortality, increased size of vital organs, loss of appetite, and occasionally other signs of chronic poisoning are evident in rats after repetitive feedings of toxaphene at a level of 100 ppm for a period of two years. Cumulative effects of poisoning in dogs, however, are noted at much lower levels of toxaphene in the diet. These variations in response among animal species coupled with the inadequacy of behavior and changes in appearance as criteria of chronic injury make it difficult to interpret laboratory data in terms of human hazard. For these reasons, histopathologic studies are being relied upon increasingly to measure the chronic toxic effects of chemicals. On the basis of such evaluations of chronic toxicity, toxaphene has been found to compare favorably with many of the chlorinated hydrocarbon and metallic insecticides, although less so in comparison with most of the botanical insecticides and the remaining synthetic insect control chemicals in common use.

In laboratory animals toxaphene in concentrated form is reported to be a mild to moderate skin irritant. A conventional patch test of human subjects yielded no evidence of irritation or sensitization. Irritation of the eyes, nasal mucosa, and throat has been reported in persons exposed to toxaphene dusts and sprays. These manifestations are believed to be caused primarily by the diluent or solvent used in the formulations.

Systemic effects may be induced by absorption of toxaphene through the skin in dry form and in solution. Absorption through abraded skin surfaces is the most rapid. Dry formulations of the insecticide are the most variable in this respect and skin hazards are dependent on several factors. The rate and extent of cutaneous absorption of such preparations depend on the concentration and extent of exposure, the presence of wetting agents (as used in wettable powders), and the susceptibility of animal species. High concentrations of dusts (50%) do not elicit symptoms in dogs, although lesser concentrations are lethal to rabbits. Wettable powder preparations have provoked symptoms in cattle, although to a lesser degree than oil solutions. Oil formulations and emulsive forms of the chemical are readily absorbed through the skin and are the most dangerous. A rapid vat-side test for assaying the amount of toxaphene in cattle dips has been developed which allows the use of dip solutions without running the risk of serious injury to the animal. It is not recommended for use on dairy cattle or in dairy barns because of the danger of milk contamination.

When it enters the respiratory tract toxaphene is potentially toxic, especially in solution. Erratic results were obtained in the available animal studies on this phase of its toxicity. Forty, 100, and 60% mortalities were obtained in groups of mice exposed to oil-based mists of toxaphene in a concentration of 0.2 mg. per 100 cc. of air per minute for 112, 116, and 158 minutes, respectively. On the basis of this test, the $L.C._{50}$ for mice is 0.2 mg. per 100 cc. of air per minute for a two-hour exposure period. Absence of significant consolidation in the lungs suggests that death was primarily caused by toxaphene. Field studies of livestock exposed to toxaphene solutions used as cattle dips indicate that the insecticide may be toxic both cutaneously and by inhalation, especially to the young of the species. Autopsy of calves dipped in toxaphene solutions showed lung involvement which was attributed to the dip solution.

Gross pathologic changes are uncommon in either acute or chronic toxaphene poisoning. Histologic studies of chronically poisoned animals revealed degenerative changes in the renal tubules and liver parenchyma. The latter are characterized by centrolobular hypertrophy of the hepatic cells which may progress to central necrosis and reparative hypertrophy. The brain, heart, lungs, skeletal muscles, adrenals, pancreas, stomach, small and large intestines, and spleen were uninjured.

Symptoms which may be anticipated in human poisoning from toxaphene are those of a convulsant drug affecting the brain and spinal cord. Generalized epileptiform convulsions are the most prominent features in acutely intoxicated animals and may be expected in human counterparts. Salivation is usually the first sign of toxicity in animals. This is followed by emesis, which is believed to be caused by direct stimulation of the emetic center. Shortly after the onset of vomiting, intermittent muscle spasms develop. These are followed by generalized convulsions at three- to five-minute intervals. Convulsions become progressively more frequent until finally a convulsive state exists which terminates in exhaustion and death from respiratory failure. The onset of symptoms usually occurs in one hour, although symptoms may be delayed as long as three or more hours after an oral toxic dose. Death occurs in four to eight hours or may be deferred up to 24 hours.

The treatment of toxaphene poisoning is directed toward the evacuation of the stomach and bowels and control of convulsions and other central nervous system manifestations. Gastric lavage and saline cathartics are the accepted measures for the removal of ingested insecticide. Toxaphene-induced convulsions in experimental animals seem to be controlled with greater ease when this practice is followed. This is probably because of the great affinity for lipoid substances and the negligible water solubility which is characteristic of toxaphene and other chlorinated hydrocarbon insecticides. Oily cathartics and fatty substances are usually contraindicated because of their capacity to increase absorption of the toxicant. Prompt removal of the oil-solubilized insecticide before passage into the intestines, however, reduces the chance for absorption of appreciable amounts of the toxicant.

A variety of drugs have been tried for the control of toxaphene convulsions. These include morphine, paraldehyde, methadone, dilantin,® tridione® with urethane, the sodium salts of amytal,® pentobarbital, and phenobarbital. All were given intravenously except paraldehyde, which was given intramuscularly, orally, and rectally. Morphine, methadone, and tridione® with urethane were found to be ineffective in experimental animals. Paraldehyde effectively controlled convulsions when given in large doses intramuscularly but produced sloughs. It was less effective by stomach and by rectum. Dilantin,® when given with small amounts of phenobarbital, was effective when given early but it was ineffective for recurrent convulsions after an initial dose of phenobarbital.

All of the barbiturates used were effective in controlling convulsions. When treatment is instituted before the onset of convulsions, long acting depressants, such as phenobarbital sodium, are the drugs of choice. If convulsions develop prior to treatment, short acting barbiturates, such as pentobarbital sodium, are considered to be more effective, since a full anesthetic dose of the drug can be given if necessary. Experience with animals indicates, however, that convulsions can be most readily controlled if treatment is begun before their appearance. Once convulsive seizures occur it is advantageous to build up the dosage of the drug as rapidly as possible to a level sufficient for control, since the longer convulsions persist the more difficult they are to control.

REPORT TO THE COUNCIL

The Council has authorized publication of the following report from the Committee on Research, a standing committee of the Council on Pharmacy and Chemistry.

R. T. Stormont, M.D., *Secretary.*

Physicians often are disconcerted by premature or sensational announcements of medical discoveries appearing in the lay press long before any authoritative information on the subject is published in a reputable medical journal. The professional resentment aroused is frequently directed against the investigators whose names are mentioned in the news release. As a rule, the investigators are not directly responsible for the appearance of the story in the national press.

The enormous interest of the public in any item concerning medical progress results in thorough coverage of the scientific meeting of any large medical society by newspaper reporters free to attend such sessions. What the reporter considers newsworthy and interesting he prints with names, pictures, and his own interpretation of the story. This is his inherent right as expressed and guaranteed in the term "freedom of the press." Nevertheless, it would seem advisable for science writers to check over the facts contained in their stories with the investigators. The latter invariably are willing to correct errors or misinterpretations of their reports in the interest of the reading public. Undue haste in publication may result in harm to both the laity and the writer's reputation for accuracy.

Another source of news stories apparently emanates from public relations counsels employed by some pharmaceutical firms to place items concerning new drugs in the newspapers. In this the public relations counsel is merely carrying out his client's wishes. The firm, however, has recognized the commercial advantage in creating a demand by the public for a new and untried drug or for a new and scantily documented use for an older drug. By such publicity the firm apparently hopes to avoid the long but necessary period of evaluation for a new method of treatment. Following publication of these planted items, the public is quick to press the profession for employment of newly mentioned drugs or uses and shows little sympathy or understanding for the reluctance and resistance of physicians to accept such publicity as evidence of therapeutic worth. There is no denying that the wisdom of releasing some of the information disseminated in newspapers and periodicals, and on radio and television, is open to question.

The concern expressed by research investigators and practicing physicians regarding the detrimental effect of many of these press releases on physician-patient relationships indicates a need to clarify the situation for the profession and to suggest means which might aid in avoiding unpleasant premature release of information.

The following article on this subject has been reviewed and approved by the Committee on Research.

Paul L. Wermer, M.D., *Secretary,*
Committee on Research.

DOCTOR, MEET THE PRESS!

John L. Bach, Chicago

Times have changed in the field of medical science reporting since Osler uttered this caution: "Believe nothing that you see in the newspapers—they have done more to create dissatisfaction than all other agencies. If you see anything in them that you know is true, begin to doubt it at once."

The medical profession's attitude toward newspaper reporters has changed from definite coolness to warm and friendly cooperation, especially since World War I.

More doctors are meeting more reporters today than ever before with the result that there is more and more news about medicine and health in newspapers and magazines and on the radio. This reflects a strong desire by the public for knowledge of the progress of medical science. Independent newspaper and press association surveys have shown that there is more reader interest in medical news than in any other branch of science.

Director of Press Relations, American Medical Association.

Therefore, the average doctor, whether general practitioner or specialist, can expect sooner or later to meet the press. It may happen while he is busy in his office or walking up the steps of the hospital or addressing a medical meeting or entertaining socially or speaking at a luncheon club. It may happen suddenly when a prominent patient dies or when the doctor plays a part in the development of a new drug.

Many physicians like to think that they meet reporters, or highly trained science writers, on a basis of equality, with the best of good will. How the doctor handles himself to meet these extraordinary situations can spell either success or failure. While medical press relations have improved tremendously during the last few years, it is still surprising how often specific encounters between physicians and science writers result in disappointment or annoyance on one side or both.

This can be blamed on the complicated aspects of both writing and reading news of scientific discoveries in medicine.

As Dr. Alan Gregg, director of the Rockefeller Foundation, said in one of his speeches not long ago: "The issue of what a discovery may eventually mean injects a tremendous emotional strain. The possible meaning of a discovery affects the investigator, the news writer, the medical profession, the anxious patient, and the news reader—each in a different way.

"The investigator's ambition to have accomplished something of undisputed and permanent value, as well as scientific soundness, is quickened—to put it rather mildly. The news writer suffers from the temptation to play up undeniable but unlikely possibilities of the discovery. The medical profession, with a long experience both of bitterly disappointing flashes-in-the-pan and almost miraculous conquests of disease, eagerly awaits confirmation and application of the new fact. The anxious patient and his family experience the anguish of uncertainty and the all but intolerable vacillation between incredulous despair and new renewed hope. Even the question of patents and proprietary control may be involved. Everyone is disturbed."

With such a tense and complicated background to the release of news of advances in medical science, both the writer and the doctor who becomes associated with an important announcement are faced with certain moral obligations.

William M. Pinkerton, director of the Harvard News Service and a newspaperman for more than a decade, once wrote an excellent piece in the Harvard Business Review on the attitudes of the public toward the press. He said that busy executives—and that includes doctors—often complain that:

"The papers never get things right." "You can't trust reporters." "They didn't put in half of what I told them." "They missed the whole point of the story." "I didn't say that at all."

The truth is, Mr. Pinkerton said, that most of the time newspapers do get things right; you can trust most reporters; they do have the space for good news; one man's point is another man's side issue; occasionally someone is misquoted, but often the real trouble is surprise at the naked look of the spoken word in print.

Why do such situations arise? The simple fact is that most of the misunderstanding, when there is misunderstanding, arises because few physicians know how reporters work or what makes them tick.

The doctor often believes that he knows all about newspapers and can determine for himself what they should say and exactly how they should say it. In reality, newspaper writing today, whether it is medical news or the reporting of a big fire, is an exacting business—as exacting as removing a gallbladder or prescribing a drug for a pain in the stomach. It is a highly competitive business. The people who run a newspaper are as well trained for their specific jobs as the doctor is in his field. Like some physicians, many consider themselves specialists in their own writing sphere. That is why newspapers have medical science writers, financial writers, sports writers, editorial writers, and outdoor editors. Each of these has special talents which he applies in his work and, over the years, becomes recognized as a specialist in a certain field or a branch of the newspaper business.

One important point to remember is that all of these writers work for an institution or business whose freedom is guaranteed under the Constitution of the United States and all of the state constitutions. Under such guaranties, the press stands by common consent first among the organs of public opinion.

Remember, too, that a reporter never stands alone. "A reporter's stake in a story is shared by his editors," said Mr. Pinkerton. "If he is pushed around and left cooling his heels in an outer office, his grievance may well become their grievance, too. No matter how hard an editor may strive to handle the news impartially or without bias, the 'bad' news source is sometimes in danger of suffering in print for his 'acts.' And the 'good' news source is likely to benefit in the long run."

A reporter's job is to report news accurately and impartially and if he is working on a medical story, for example, he naturally turns to a doctor for the facts. He should turn to the medical profession for his information because presumably it is the best informed and should always be considered the most authoritative source. A reporter is not expected to mold the results to some pre-conceived notion—yours or his.

The facts about American medicine and the health of the American people have to be told by those who know the facts. If the reporter cannot get the facts from you, the doctor, he will go elsewhere and your chances and the chances of the medical profession, generally, of getting an accurate story before the public may be lost.

"Physicians must realize that what the public knows and how the public feels toward the profession depends largely upon where it gets its information," said C. Lincoln Williston, Manager of the University of Illinois' Office of Public Information, adding: "If physicians and medical societies do not facilitate the publicizing of the authentic information which they possess, they then must accept the blame for public ignorance and public misunderstanding.

"The fact must be recognized that, no matter what physicians and scientists might accomplish, newspapers, magazines, radio and television are going to report on subjects currently within the realm of medicine. The choice then is not between publicity and no publicity. Rather, it is the choice between authentic news reports prepared with the active cooperation of physicians on the one hand, and 'black market' publicity of questionable accuracy on the other."

Someone once said that if doctors, especially research men whose business is the accumulation of knowledge, do not accept their educational responsibilities, they will have abdicated in favor of ignorance.

The framers of the "Principles of Medical Ethics of the American Medical Association" must have had this thought in mind when they drafted the following section:

"Many people, literate and well educated, do not possess a special knowledge of medicine. Medical books and journals are not easily accessible or readily understandable.

"The medical profession considers it ethical for a physician to meet the request of a component or constituent medical society to write, act or speak for general readers or audiences. The adaptability of medical material for presentation to the public may be perceived first by publishers, motion picture producers or radio officials. These may offer to the physician opportunity to release to the public some article, exhibit or drawing. Refusal to release the material may be considered a refusal to perform a public service, yet compliance may bring the charge of self-seeking or solicitation. In such circumstances the physician should be guided by the decision of official agencies established through component and constituent medical organizations.

"A physician who desires to know whether, ethically, he may engage in a project aimed at health education of the public should request the approval of the designated officer or committee of his county medical society." In order for a physician to comply with the last statement, it is imperative that every state and county medical society have an active press relations committee, empowered to speak, which can serve effectively as the liaison between physicians and the press, magazines, radio or television.

Recognizing the importance of full cooperation between physicians and the press, many of the state and county societies have adopted a Code of Cooperation, setting forth a workable policy on medical news which would satisfy both sides.

The Colorado State Medical Society's Code, which has served as a model for Codes adopted in many of the other states, sets up a system of official spokesmen for each county society—usually the president, secretary and publicity chairman. These men and women, as well as the spokesman for the hospitals, are to make themselves available to the press and may be quoted "in matters of public interest for purposes of authenticating information." The Code states specifically that this action by the spokesmen "shall not be considered by their colleagues as a breach of the time-honored practice of physicians to avoid personal publicity, since it is done in the best interests of the public and the profession."

The Colorado Code and the Codes in effect in many of the other states are a tremendously encouraging sign that the physicians and the press are alive to the importance of giving accurate medical information to the public. The Codes, however, should be drafted cooperatively between the press and medical societies; they should never be drafted by the medical society alone.

A doctor or medical researcher, in order to make his job of meeting the press easier and, at the same time, stay within the bounds of good ethics, should call upon such a committee of his state or county society for help in working out publicity problems. In most states, the publicity committee is guided in its work by experienced public relations people, most of whom are former newspapermen. The job which these committees are doing, and have done, is of great import to the medical profession as a whole.

But the Codes in themselves do not provide all the answers to publicity problems on a local or national level. Their effectiveness rests on whether the publicity committee is an active one or a dead one. An active committee, really interested in the day-to-day problems that come up, will do a good job, while an inactive committee, one in name only, will do a poor job which will show up continually in bad public relations for the profession.

National medical organizations, especially the specialty groups, and at least the larger state societies, should by all means set up the physical mechanics for doing a good press relations job at their annual meetings. Sometimes bad publicity emanates from national meetings and this bad publicity usually can be traced to poor press relations on the part of the medical organization. The blame cannot be laid on the press alone.

The job of handling press relations at a national meeting requires, above all things, experienced personnel fully familiar with both the doctor's viewpoint and that of the press. The experienced press representative can save the doctor many a headache. Physicians who specialize more or less in research are often invited to appear on a program of a national organization. But, at times, they are almost reluctant to give information to their fellow physicians because they fear that a garbled story might appear in the newspapers, resulting in ridicule by their colleagues because of the consequent publicity. This is a pertinent point in the whole realm of medical press relations. But there is more to it than that. Even if a news story is 100% accurate, physicians will frequently deride their colleagues who figure in a story with such a jibe as: "I saw your advertisement in the paper today." Such a statement, good natured or not, makes the conscientious physician, who is trying to help the profession, quite reluctant to be a part of any future stories. This hurts medicine!

It is much easier for everybody concerned if the doctor can consult in advance with the press representative who has been empowered by the national organization to handle its press job.

In cases where no such representative is available at a national meeting, it is best for the doctor to consult or work with the public relations director of the medical society located in the city where the meeting is being held. In all probability this man is well acquainted with the newspaper contacts in that city and can be of invaluable help to the visiting doctor.

Several national specialty organizations still adhere to the time-honored custom of mimeographing in advance the full papers which doctors are scheduled to deliver at a meeting. This is a good and bad practice—depending on the way a newspaperman and a doctor look at the service from their own individual standpoints.

Some writers who devote their full time to science and medicine, prefer the full texts; the more the better. Other writers, especially those on newspapers, prefer to work from good abstracts of the papers because they do not have the time to review the full texts of all papers.

The majority of writers, however, would prefer to work from abstracts carrying interpretive scientific facts, definitions and background. "If a doctor's contribution is an important and interesting one," a prominent writer told me, "nothing takes the place of a full text." He was of the opinion that many of the inaccuracies in a story resulted because a reporter, working from an abstract only, tried to fill in the gaps himself.

For any medical organization to adopt a policy of automatically mimeographing all papers in full is the laziest way of handling a press relations job. But it does not help the physician who prepared his paper with only a medical audience in mind. The doctor may be discussing a subject based on only a handful of cases; yet his experimental research may be important enough to present to the medical meeting even though he knows it is "premature" in every sense of the word. In such a case, the physician is presenting his facts to his colleagues only and not to the public. For any organization to follow a general practice of mimeographing such a paper and passing it on to writers, without first weighing its impact on lay readers, is to do a disservice not only to the doctor who was invited to deliver the paper, but to the medical profession and the public as well.

Whether to provide a full text or an abstract only is best determined by the common sense and good judgment of an experienced person, who carries the responsibility of handling the press relations for a medical organization.

Abstracting of medical material for publicity purposes only should be the responsibility of the national or state organization if they are interested in doing a good press relations job. By having an experienced medical press writer abstract the papers in advance in newspaper phraseology, the organization is, almost automatically, assured more accuracy when the final story appears in print. By the same token, the doctor who is involved in the story often avoids embarrassment by having his facts appear in public print correctly.

A physician who is a party to an important announcement, not necessarily given at a national or state convention, should in the best interest of ethics seek the advice of the publicity committee of his local medical society well in advance. In addition, he should seek the advice and help of a press writer experienced in the medical field who can aid him immeasurably in presenting his case to the publicity committee. Then, if the committee grants its approval, the writer also can help the physician to prepare a proper press release. The extra effort which the physician exerts in advance will pay off in a more accurate story—a story he can proudly and properly endorse.

Since he usually lacks experience in preparing or presenting facts for lay consumption, a doctor should rarely prepare his own news release. This is true especially with statements pertaining to cancer, poliomyelitis, heart disease, arthritis, and asthma. The public is vitally interested in these subjects and news stories dealing with them should be carefully handled so that they do not imply that a cure has been found unless, of course, the word "cure" with all its full meaning is actually involved.

In reporting drugs for the treatment of some of these diseases, pharmaceutical firms are often censured by members of the medical profession, who charge, among other things, that the announcement is premature. The highly ethical drug firms are seldom responsible. Most of the time they leave no stone unturned in trying to keep a premature story out of print. Many times they fail because the news leaks out from a wholly unsuspected source. Then, again, there are less reputable firms which rush into print with the most flimsy reports based on few, if any, scientific facts or on articles "in press" and therefore unavailable to the physician to enable him to make an independent appraisal of the worth of the drug. These bad reports offset the really good reports.

Some physicians seem to feel that nothing should be said in the public press about a new therapeutic agent until it has been "fully proved." But when is a drug "fully proved?"

Mr. Steven M. Spencer, popular medical editor of *The Saturday Evening Post*, discussed the matter of "premature" publicity in a fairly recent article in *New York Medicine*. He said:

"We know that very few contributions represent immortal and immutable medical truths. But that does not mean they are not worthwhile contributions, capable of giving valuable aid until something better comes along. Sulfanilamide was not without its untoward side effects, and ultimately it was largely replaced by other, better chemotherapeutics. Yet in the meantime it saved many lives and prevented much suffering. Would those who charge the press with being 'premature' in its reports have denied the public information about sulfanilamide simply because it had some drawbacks?

"No informed person expects science to move forward at a steady, unchanging pace. It is inevitable that medicine may occasionally take three steps upward and then find it must back down one step to secure a firmer foothold—but it has made a net gain of two steps. Surely the public is entitled to witness this progress, no matter how irregular and interrupted it may be. It is the science writers' contention that the public should learn of new developments touching on its health just as soon as a number of qualified physicians feel that the developments have promise and that they have been *tried out sufficiently to justify continued use.* Those who are ill need all the hope and encouragement they can find, and they find a great deal in the good news of medicine's accomplishments. The disease which a patient is suffering may be incurable today, but his faith in medical science may help sustain him until the arrival of tomorrow's successful treatment."

A few physicians like to represent themselves as knowing everything there is to know about medicine, and they are quick to criticize any newspaper announcement about a drug or technic unknown to them. A moment's reflection will show that such a position is indefensible because the diversity of specialties in medicine is so great today that no one can assume he knows everything about all of them.

Consequently, to the patient inquiring about a new drug reported in the press but not yet in a medical journal, the physician might say something like this: "It's new and I hope what I read in the paper, too, is true. I haven't seen anything about the drug in the medical literature, but I'll do some checking and try to appraise it in your particular case. Please give me a little time and I'll see if it is a safe treatment for you."

The patient will appreciate the doctor's position and will respect his attempt to exercise his own personal judgment in evaluating the drug for the patient's use. There is certainly nothing embarrassing in such an explanation.

The careful reporter often qualifies his story by warning of dangers and short supply of a new substance or insufficient evidence. Physicians should look over the published story rather carefully and use such qualifications to calm the patient who calls.

Another bugaboo to an accredited medical science writer is the doctor's reticence at seeing his name in the public print. He prefers to stick by the tradition of hiding his light under the proverbial bushel labeled "Don't quote me."

Again Mr. Spencer says: "Our argument for using names is simply that we believe the public has a right to know whose work is being described and whose opinions are reflected in the text of the article. To adopt a policy of not quoting authorities would open the way for unreliable reports on medicine by irresponsible publications—and there are a few. In addition, we feel the story of medicine's advance is the story of people as well as of facts."

Some doctors who protest against the use of their names in a news story claim that such publication amounts to personal glorification and advertising and that this type of publicity can become a device whereby charlatans promote their own trade.

Many doctors would prefer to remain anonymous, but Lester Grant, former science editor for the *New York Herald Tribune* and now a medical student at Harvard, believes this is really a dangerous line of thinking. "A doctor's name in a story," he said, "is some protection for the public; at least, it's a check against careless reporting. Without having to worry about where he got his information, the reporter might be led to the following fantasy: 'A cure for cancer has been discovered, it was learned last night. This cure involves the drinking of a quart of water a day, elimination of pepper from the diet, and strict bed rest for 19 years.' If a doctor protests against the spreading of such nonsense and demands to know the source of the information, the writer might stand on his professional ethics, so called, and refuse to give the name of his informant. Such hyperbole may seem out of reach, even of some of the less responsible newspapers, but one has only to track down the sources of some of those 'reliable' reports coming from 'well informed spokesmen' to appreciate the risk of doing this sort of thing in science stories."

From the standpoint of newspapers and magazines, good pictures are just as important as the text of a story. Both usually maintain elaborate photographic departments. The photographer is on much the same level of the working newspaper ladder as the reporter. You cannot work with one and ignore the other because their assignments probably come from the same source—the editor.

What are the photographers' common complaints against doctors? Well, here are two examples of how best to "burn" a photographer. When he calls and asks to take your picture, say "yes" in a friendly, cordial way. Then, after he spends an hour getting to your office or meeting, tell him you have changed your mind because "it may be unethical." Or, if you do consent and he spends considerable time setting up his camera and lights, tell him as he starts posing you that he can only take a picture of the back of your head; side or front view shots are out. Just visualize a photographer's frustration!

This all makes for bad public relations toward the medical profession, and such problems should no longer have a place in present-day medical reporting.

When the photographer makes his original request, the physician should refer him to the chairman of the publicity committee of his local society, assuming that the committee is an active one and not serving in name alone. He should provide the photographer with the chairman's name, address, and phone number and invite him to contact the chairman, explaining the reasons for the procedure. In turn, the chairman and/or his committee should inform the photographer of their decision in a comparatively short time, preferably immediately. The less time the better. There is nothing more disconcerting to a photographer than to make a request for a picture and not have the publicity committee act for two or three days. The photographer, like the writer, has a deadline to meet and time to him on any assignment is an important consideration.

If the photographer makes his request of the doctor during a medical meeting where the physician appears on the program, it might be more expedient and feasible for the matter to be referred to the organization's public relations man or press relations contact, both of whom are fully aware of the necessary protocol.

A short time ago a physician read an interesting paper before a national specialty society. The next morning a newspaper carried a story, based on his paper, on the first page. That afternoon a national news magazine requested his picture. The doctor refused on the basis of medical ethics; actually he felt that if the picture appeared, along with the story, in a national magazine he would be held up to ridicule by his colleagues. The photographer contacted the local medical society. Again permission to take the picture was turned down without even checking or weighing the facts with the society's publicity committee. The photographer's persistence finally got the matter to the attention of the society's publicity chairman who, without apparently being acquainted with the actual interpretation of the Principles of Medical Ethics, turned down the request, too.

It would not have been unethical for the committee to grant the photographer permission to take the doctor's picture. The whole matter could have been handled in a matter of minutes. As it turned out, the photographer was given a harmful runaround by people who apparently did not want to be bothered.

Since the doctor had given his paper before an open meeting of an ethical medical society, the photographer was within his rights in requesting the picture. If he had taken the picture while the doctor was delivering his address, neither the doctor nor the medical group could have done anything about it. In refusing permission in this case, the publicity committee was responsible for doing a disservice, publicitywise, to the medical profession as well as to the news magazine.

The committee apparently was unaware of the sentence in the Principles of Medical Ethics which reads: "Refusal to release the material may be considered a refusal to perform a public service . . ."

Generally speaking, the job of handling medical press relations can be boiled down to this:

It is considered unethical for a physician to furnish a story or picture on his own initiative to newspapers or magazines, as this smacks too much of self-seeking publicity. On the other hand, if data have been or are being presented publicly in lay or scientific meetings, it is considered ethical if the physician works through the publicity committee or public relations man of his local society. In that way, his colleagues are his judges and, in abiding by their judgment, he cannot be accused of being a publicity seeker.

Investigators associated with medical schools are obligated to conform to the procedures established by their institutions for dealing with reporters and publicity through public relations officials appointed by their institution. It must be emphasized, however, that under the existing code of ethics this procedure does not relieve the investigator of the responsibility of clearing the release with the publicity committee of the local society. Should the latter rule after publication that release of the data is unethical, the physician, not the medical school's public relations council, is held responsible for violation of the code.

Emergency situations often arise in which the time relation between the story already presented at a meeting and its "going to press" make such referrals impossible. In such a case, where decision on publication is no longer in the hands of the physician, he should still make every effort to assure accuracy of the data contained in the news release by working in conjunction with the publicity committee of his county society.

NEW AND NONOFFICIAL REMEDIES

The following additional preparations have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application.

R. T. Stormont, M.D., *Secretary.*

Estrone-U.S.P. (See New and Nonofficial Remedies 1952, p. 332).

Kremers-Urban Company, Milwaukee

Solution Estrugenone in Oil: 1 cc. ampuls and 10 cc. and 30 cc. vials. A solution in sesame oil containing 1 mg. (10,000 I.U.) of estrone in each cubic centimeter. Preserved with 0.5% chlorobutanol.

10 cc. vials. A solution in sesame oil containing 2 mg. (20,000 I.U.) of estrone in each cubic centimeter. Preserved with 0.5% chlorobutanol.

Suspension Estrugenone with Benzyl Alcohol 2%: 1 cc. ampuls and 5 cc. and 10 cc. vials. A suspension in 60% propylene glycol containing 5 mg. (50,000 I.U.) of estrone in each cubic centimeter.

Suspension Estrugenone with Procaine Hydrochloride 1%: 1 cc. ampuls and 10 cc. vials. A suspension in 15% propylene glycol containing 2 mg. (20,000 I.U.) of estrone in each cubic centimeter. Preserved with thimerosal 1:10,000.

Progesterone-U.S.P. (See New and Nonofficial Remedies 1952, p. 348).

The Bio-Intrasol Laboratories, Inc., Brooklyn

Aqueous Suspension Progesterone with Procaine Hydrochloride 1%: 10 cc. vials. An aqueous suspension containing 10 mg. or 25 mg. of progesterone in each cubic centimeter. Preserved with thimerosal 1:10,000.

Solution Progesterone in Oil with Benzyl Alcohol 2%: 10 cc. vials. An aqueous suspension containing 10 mg. or 25 mg. of progesterone in each cubic centimeter. Preserved with thimerosal 1:10,000.

The Upjohn Company, Kalamazoo, Mich.

Aqueous Suspension Progesterone: 1 cc. and 10 cc. vials. A suspension in isotonic salt solution containing 25 mg. of progesterone in each cubic centimeter. Preserved with thimerosal 1:10,000.

Mephenesin (See New and Nonofficial Remedies 1952, p. 432).

C. B. Kendall Company, Indianapolis

Tablets Mephenesin: 0.25 gm. and 0.5 gm.

Diphtheria Toxoid, Aluminum Phosphate Adsorbed.—Aluminum phosphate adsorbed diphtheria toxoid is a sterile suspension of diphtheria toxoid adsorbed on aluminum phosphate. It is detoxified and standardized for potency as described in the monograph on Diphtheria Toxoid, Aluminum Hydroxide Adsorbed. Diphtheria Toxoid, Aluminum Phosphate Adsorbed, complies with the official potency and other requirements of the National Institutes of Health of the United States Public Health Service.

Actions and Uses.—See monograph on Diphtheria Toxoid, Alum Precipitated. Because of the physical character of the adsorbed product, absorption is delayed.

Dosage.—See monograph on Diphtheria Toxoid, Alum Precipitated.

Parke, Davis and Company, Detroit

Diphtheria Toxoid, Aluminum Phosphate Adsorbed: 0.5 cc. vials (one injection), 1 cc. vials (one immunization; two 0.5 cc. injections), 5 cc. vials (five immunizations). Preserved with thimerosal 1:10,000.

Penicillin for Injection for Prolonged Action (See New and Nonofficial Remedies 1952, p. 126).

Irwin, Neisler & Company, Decatur, Ill.

Aqueous Suspension Procaine Penicillin G: 10 cc. vials. A suspension containing 300,000 units of procaine penicillin G in each cubic centimeter. Preserved with 0.18% methylparaben and 0.02% propylparaben.

Procaine Penicillin G in Oil: 10 cc. vials. A suspension in sesame oil containing 300,000 units of procaine penicillin G in each cubic centimeter with 2% aluminum monostearate.

Thiopental Sodium-U.S.P. (See New and Nonofficial Remedies 1952, p. 246).

Abbott Laboratories, North Chicago, Ill.

Pentothal Sodium: 10 gm. multiple dose ampuls. Buffered with 0.6 gm. of anhydrous sodium carbonate.

Penicillin for Oral or Sublingual Administration (See New and Nonofficial Remedies 1952, p. 122).

Premo Pharmaceutical Laboratories, Inc., South Hackensack, N. J.

Tablets Penicillin G (Buffered): 200,000 units. Buffered with calcium carbonate.

Citrated Normal Human Plasma-U.S.P. (See New and Nonofficial Remedies 1952, p. 200).

Junior League Blood Center of Milwaukee, Inc., Milwaukee

Normal Human Plasma (Citrated): Equivalent to 250 cc. of pooled plasma containing 5% dextrose.

***p*-Aminosalicylic Acid** (See New and Nonofficial Remedies 1952, p. 87).

Gold Leaf Pharmacal Company, New Rochelle, N. Y.

Tablets Para-Pas: 0.5 gm.

Estrogenic Substances—Conjugated (See New and Nonofficial Remedies 1952, p. 338).

Eli Lilly & Company, Indianapolis

Tablets Konogen: 0.625 mg., 1.25 mg., and 2.5 mg. U. S. Patent 2,429,398.

Penicillin for Inhalation (See New and Nonofficial Remedies 1952, p. 121).

Abbott Laboratories, North Chicago, Ill.

Soluble Tablets Potassium Penicillin G: 250,000 units.

Diiodohydroxyquinoline-U.S.P. (See New and Nonofficial Remedies 1952, p. 154).

G. D. Searle & Company, Chicago

Tablets Diodoquin: 0.65 gm. U. S. Trademark 336,484.

METABOLISM OF FRUCTOSE IN THE DIABETIC

It has been known for some time that the administration of glucose to dogs or normal human subjects leads to an increase in the pyruvate concentration and a decrease in the level of inorganic phosphate in the blood. These changes also occur when a diabetic patient receiving insulin is given glucose. The increase in the blood pyruvate, coupled with a decrease in inorganic phosphate content, has been used as an index of the metabolism of administered sugar.

Recently, a series of studies[1] on the metabolism of intravenously administered fructose in normal and diabetic subjects has been reported. The changes in the blood concentration of fructose, pyruvate, and inorganic phosphate following an intravenous injection of fructose indicates to these investigators that the metabolism of fructose is different from that of glucose in both normal subjects and diabetic subjects without insulin. After giving fructose to either group there is an increase in pyruvate concentration in the blood with a concurrent decrease in inorganic phosphate level. While the intravenous administration of fructose to a diabetic subject without insulin invokes a large and rapid increase in the pyruvate concentration in the blood, glucose given in a similar manner causes either a slight or a delayed increase in pyruvate. This was interpreted as indicating that the diabetic subject without insulin can metabolize fructose given intravenously in a manner similar to a normal person.

By using the technique of hepatic vein catheterization, Craig and associates[2] studied the metabolism of fructose in the liver of diabetic and nondiabetic persons. Following the intravenous administration of fructose, they found that the livers of both groups of subjects removed large amounts of fructose from the blood. Also, livers of the diabetic and nondiabetic subjects produced increased amounts of pyruvic acid after the injection of fructose. In the absence of ketosis, the liver of the diabetic subjects was found to metabolize fructose in a manner similar to that in the nondiabetic person; however, when ketosis occurred there was a normal uptake of fructose but a decreased production of pyruvic and lactic acids.

The investigations on the metabolic aberration in diabetes have yielded promising information in recent years, particularly since the Embden-Meyerhof scheme for the anaerobic breakdown of glucose has been widely accepted. Since fructose normally enters the scheme of glycolysis subsequent to the point at which glucose is phosphorylated, these studies on the metabolism of fructose are consistent with the concept that the phosphorylation of glucose to glucose-6-phosphate is impaired in the diabetic. The phosphorylation of fructose, on the other hand, appears to proceed at its normal rate in the diabetic without insulin.

BLOOD TRANSFUSION IN IRRADIATION HEMORRHAGE

The threat of atomic warfare and the ever-increasing peacetime exploitation of atomic energy have focused attention on the necessity for developing methods for the control or prevention of irradiation injury in man. The mortality in animals exposed to high levels of irradiation has been reduced by the administration of the broad spectrum antibiotics,[1] by early exchange transfusion,[2] by parabiosis,[3] or by the implantation of fresh splenic tissue or the injection of spleen homogenates.[4] In contrast, while the use of frequent whole blood transfusions would seem a logical method of combating the thrombocytopenia and anemia in the abnormal bleeding syndrome of irradiation sickness, Allen and his associates have shown that in dogs such transfusions not only are ineffective but may in some instances actually be harmful.[5] The University of Chicago investigators exposed 173 dogs to single doses of total body x-radiation at dosage levels ranging from 175 to 450 r and compared the survival times of control animals and of animals given three transfusions a week with compatible blood. They found that the animals that received transfusions survived no longer than the controls and at autopsy displayed as many areas of gross hemorrhage. Furthermore, while blood transfusion did benefit to some extent the irradiation anemia, it did not correct the thrombocytopenia or leukopenia and failed to prevent or control the postirradiation increase in whole blood clotting time. In some animals, the transfusions appeared to exert a deleterious effect, possibly owing to transfusion reactions, which, according to the authors, occur much more frequently in irradiated than in nonirradiated dogs.

P.: Protection of Mice Against X-Irradiation by Spleen Homogenates Administered After Exposure, Proc. Soc. Exper. Biol. & Med. 80: 112 (May) 1952.

[5] Allen, J. G., and others: Blood Transfusion in Irradiation Hemorrhage, Science 115: 523 (May 8) 1952.

Allen and his co-workers point out that, since the status of blood types and transfusions in dogs is as yet ill-defined, the failure of frequent blood transfusions to prolong the survival time of irradiated dogs does not necessarily mean that such measures would be ineffective in man. Furthermore, they emphasize that their results do not relate in any manner to the use of blood in the treatment of shock incident to the early blast effects of an atomic burst or to blood needs in anoxic anemia. On the other hand, they feel that on the basis of their results a more cautious attitude toward the use of frequent transfusions alone as a therapeutic measure in the treatment of the latent symptoms of irradiation in man may be indicated.

MOVIE PORTRAYS DOCTOR AT WORK

RKO-Radio Pictures has just released a 15 minute documentary film called "Your Doctor" to commercial theaters throughout the country. The film portrays a story that is one of the finest tributes ever paid to the medical profession.

The picture, which was prepared with the assistance of the American Medical Association, reveals the high quality and ready availability of medical care in this country. In cities and towns American physicians may be virtually around the corner, but in the mountains of Hickory Nut Valley, N. C., the work of a 37-year-old general practitioner, George Bond, exemplifies what doctors are doing in hundreds of rural communities. The story behind the movie is built around Dr. Bond, who has realized a life-long ambition—the establishment of the Valley Clinic and Hospital, one of many institutions supplying the best in medical care to remote areas.

The movie ends with this conclusion: "In the lives of men and women who practice the art and science of medicine is realized the noblest of human aspirations. For long ago it was said that in no other act does man approach so near the gods as when he is restoring the sick to the blessing of health."

RKO, which is trying to book "Your Doctor" in as many local theaters as possible, estimates that the film will be shown during 1952 in about 3,000 theaters, reaching an audience of 10 to 15 million persons. However, that audience can be doubled if physicians throughout the country help publicize local showings. County and state medical societies are being asked to cooperate in any way possible with theaters showing "Your Doctor." If the film is being shown in your community, urge your patients and friends to see it. The theater manager will suggest other ways in which you can help.

"Your Doctor" is an inspiring story for the lay public, and, as a result, the medical profession will benefit immeasurably if a large segment of the U. S. population sees it. The picture dispels many misconceptions about doctors; for that reason it is imperative that everything possible be done to help local theaters build a sizable audience.

NUTRITION AND THE OLDER ADULT

As time passes and the life expectancy of our population slowly increases, some apprehension appears with respect to the physiological well-being of the older adults. This group is not characterized by age in years alone but rather by a discernible decline in physical vigor and activity. Because of the lack of precise evaluation of the problem, the nutrition during later years of life has attracted considerable attention, and one recent comment[1] presents a well-considered point of view. The general principles governing the planning of a diet for the aged are not different from those for other age groups. The subjects themselves often plan their dietary program in the pattern of their youth, a period before the foundations of good nutrition were firmly established. Furthermore, because there is diminished physical activity, less food is required, and interest in food lags when mastication is difficult or digestive activity is retarded. Chronic disease, combined with economic and psychological factors, operates to develop an over-simplified dietary program, one that is too frequently deficient in protective foods.

In the light of a decreased need for energy, the daily caloric value of the diet often can be surprisingly low; older women frequently are in nitrogen balance and maintain weight on 1,500 calories or less, and men maintain weight on 2,000 calories or less. Certainly, the commoner tendency toward obesity is to be decried. There is little evidence for the need for increased consumption of protein in the elderly. Because of the tendency toward a relationship between serum cholesterol and atherosclerosis and because of the parallelism between dietary fat and the level of serum cholesterol, it appears prudent to decrease the proportion of fat in the diet in the later years of life. While there is little evidence that older adults have different requirements for vitamins, it does seem wise to allow generous amounts of iron and of calcium in the diet of the aged.

In the aged, it is quite likely that under conditions of restricted activity and the associated diminished food intake the resultant intestinal residue will not stimulate the one-a-day bowel movement that has become the popular goal in this respect. In no other connection does habit and mental attitude play a larger part than with defecation. The same program of education that will protect the older person from the alluring claims of the food-faddist should reassure him that the natural roughage in the fruit, leafy vegetables, and whole grain cereals of a good diet will promote satisfactory intestinal evacuation. All the aspects of nutrition in the later years of life merit continued study.

PENNSYLVANIA

Society News.—Effective Sept. 6 the name of the *Pittsburgh Medical Bulletin* will be changed to the *Bulletin of the Allegheny County Medical Society.*——The Pennsylvania Academy of General Practice recently installed as president Dr. Anthony T. Merski of Erie.

Hospital Retirements.—Twelve staff members, with a total of 428 years of hospital service, have retired from the medical and surgical staffs of Harrisburg Hospital. They will, however, remain as consultants of the hospital and will continue their private practice. They are Drs. Harvey F. Smith, aged 81, with 52 years of hospital service; George F. Gracey, 78; George H. Seaks, 75; George R. Moffitt, 73; Park A. Deckard, 71; Carson Coover, 70; Norman B. Shepler, 69; Joseph W. Shaffer, 69; Harry M. Kirkpatrick, D.D.S., 68; Allen Z. Ritzman, 67; Frank F. D. Reckord, 66; and George L. Laverty, 65.

Philadelphia

University News.—Dr. Victor C. Vaughan III, formerly assistant professor of pediatrics in the Yale University School of Medicine, New Haven, Conn., has been appointed associate professor of pediatrics in the Temple University School of Medicine.——Dr. John B. Levan, chief of the cardiology department of St. Joseph's Hospital, Reading, has been named as assistant professor of medicine at the Woman's Medical College in Philadelphia. Dr. Levan is president of the Pennsylvania Heart Association and has been supervising graduate courses in cardiology in 10 cities for the Medical Society of the State of Pennsylvania.

Pittsburgh

Society News.—The Pittsburgh Urological Association has elected the following officers for the coming year: Dr. Joseph G. Moore, president; Dr. William C. D. McCuskey, Wheeling, W. Va., president-elect; and Dr. Conrad A. Kuehn, secretary-treasurer.

TEXAS

Inaugurate Preceptor Plan.—Texas physicians are putting into practice a plan for placing senior medical students of the University of Texas Medical Branch in Galveston, in the homes of family doctors for 11 weeks. They will accompany their preceptor on hospital rounds, in the operating room, during office interviews, on house calls, and during emergency visits. All preceptors are members of the Texas Academy of General Practice.

Controlled Polio Experiment.—A 10 day controlled experiment was instituted on July 2 on 35,000 children, aged 1 to 6, half of whom received injections of gamma globulin. Of the eight clinics set up in Harris County to handle the experiment, five are in Houston. The $500,000 project, which is being conducted by Dr. William McD. Hammon, professor of epidemiology at the University of Pittsburgh, assisted by Dr. Lewis L. Coriell, medical director of the Camden (N. J.) Municipal Hospital for Contagious Diseases, and Helen Moore of the Detroit Department of Health, is financed by the National Foundation for Infantile Paralysis. Similar experiments were undertaken in Utah last summer with 5,768 children. According to the U. S. Public Health Service, for the week ended June 28 there were 206 cases of polio in Texas, as compared with 62 for the week ended June 30 last year.

HAWAII

American of the Week.—Dr. Robert B. Faus, Honolulu, chairman of the advisory council to the governor of civil defense, was recently selected as "American of the Week" by the American Way Committee of the Honolulu Chamber of Commerce.

Dr. Holmes Lectures in Orient.—Dr. William J. Holmes of Honolulu has returned from a tour of the Far East and India. He was guest speaker at the annual All India Ophthalmologic Conference, and in New Delhi and Bombay spoke before the local ophthalmologic societies; at Vellore he served as visiting professor of ophthalmology at the Christian Medical College. In Japan Dr. Holmes served as a special ophthalmic consultant to the Surgeon General.

GENERAL

Narcotics Bibliography.—A comprehensive list of books and journal articles dealing with drug addiction, compiled by the library of the New York Academy of Medicine, is being issued jointly by the academy and the Welfare Council of New York City. It is available from the council, 44 E. 23rd St., New York 10, for 50 cents.

Society Election.—At the annual meeting of the American Association for Cancer Research in Detroit, Dr. Stanley P. Reimann, director of the Institute for Cancer Research, Philadelphia, was elected president; Dr. Harold P. Rusch, professor of oncology, University of Wisconsin Medical School, Madison, vice-president; and Hugh J. Creech, Ph.D., of the Institute for Cancer Research, Philadelphia, secretary-treasurer.

Trudeau Society Desires Papers.—The American Trudeau Society, medical section of the National Tuberculosis Association, invites the submission of abstracts of scientific papers for representation at its next annual meeting in Los Angeles, May 18-22, 1953, at the Hotel Statler. For information write to the Chairman of the Medical Sessions Committee, American Trudeau Society, 1790 Broadway, New York 19.

Prizes for Cancer Research.—At its annual meeting the American Association for Cancer Research presented Anna Fuller Memorial Prizes "for outstanding and original research on the role of viruses in cancer" to Dr. F. Peyton Rous, Rockefeller Institute for Medical Research, New York; Dr. Francisco Duran-Reynals, Yale University School of Medicine, New Haven, Conn.; and Dr. Richard E. Shope, Merck Institute for Therapeutic Research, Rahway, N. J.

Ida Scudder International Grant.—The American Association of University Women announces the Ida S. Scudder International Grant of $500, a gift of the Scudder Association, to help a woman physician from India to study in the United States. Dr. Scudder, who in 1918 founded the Vellore Christian Medical School for women, celebrated her golden jubilee of medical work in India in 1950. The school, now affiliated with the University of Madras, has recently admitted men students.

Lecturers Wanted for Foreign Countries.—Through its secretary general, Dr. Louis H. Bauer of Hempstead, N. Y., President of the American Medical Association, the World Medical Association requests national medical associations to notify the secretariat when well-qualified physicians are planning visits to foreign countries and desire to give lectures in the countries they are visiting. Such information should be sent to Dr. Louis H. Bauer, Secretary General, The World Medical Association, 2 E. 103rd St., New York 29.

New Health Chief for Virgin Islands.—Gov. Morris F. de Castro recently announced the appointment of Dr. Roy A. Anduze as commissioner of health for the Virgin Islands and as chief municipal physician for the municipality of St. Thomas and St. John. Dr. Anduze served his internship at Freedman's Hospital, Washington, D. C., where he was assistant resident in gynecology and obstetrics. He was appointed to the staff of Fredericksted Hospital as municipal physician of St. Croix in 1940, and was made director of the venereal disease control program at St. Thomas in 1942.

Society News.—At the annual meeting of the American Pediatric Society at Old Point Comfort, Va., May 6-8, Dr. Irvine McQuarrie, Minneapolis, was elected president; Dr. Ernest J. Caulfield, Hartford, Conn., vice-president; Dr. Aims C. McGuinness, Philadelphia, secretary-treasurer; Dr. Stewart H. Clifford, Brookline, Mass., recorder; and Dr. Henry G. Poncher, Chicago, member of the council. Dr. Richard W. B. Ellis, Edinburgh, Scotland, and Sir James Spence, Newcastle upon Tyne, England, were elected honorary members of the society. The John Howland Award for distinguished service to pediatrics was bestowed on Dr. Edwards A. Park, Baltimore.

Elizabeth Blackwell Awards.—Five American women physicians have received the annual Blackwell awards of the New York Infirmary for significant contributions to the practice and teaching of medicine. The citations were bestowed on Ethel C.

Dunham, adjutant professor of pediatrics, Georgetown University School of Medicine, Washington, D. C., for study and improved care of premature infants; Edith L. Potter, assistant professor of pathology (obstetrics and gynecology), University of Chicago School of Medicine, for her work in infant pathology; Annie V. Scott of the American Presbyterian Mission, Cheeloo University School of Medicine, Tsinan, Shantung, China, for the practice and teaching of pediatrics in foreign missions; Martha M. Eliot, chief of the Children's Bureau, U. S. Dept. of Labor, Washington, D. C., for her contributions to child welfare and international public health; and to Catharine Macfarlane, research professor of gynecology, Woman's Medical College of Pennsylvania, Philadelphia, for achievements in the practice of gynecology, in cancer research, and in medical education.

Prevalence of Poliomyelitis.—According to the National Office of Vital Statistics, the following number of reported cases of poliomyelitis occurred in the United States, its territories and possessions in the weeks ended as indicated:

CANADA

Cerebral Palsy Clinic.—The Edmonton Cerebral Palsy Association recently opened a clinic in Edmonton, Alberta, where children can be taken for therapy as well as school work. The clinic represents the cooperative efforts of the public, who contributed funds for its establishment; the Alberta Health Department, which supplied the staff and much of the equipment; an Edmonton lumber company, which constructed and donated special chairs; an Edmonton club, which provided a bus to transport the children to and from their homes; and city firemen who volunteered as drivers.

FOREIGN

Anti-Tuberculosis Campaign in Arabia.—A BCG vaccination campaign against tuberculosis in Aden, Arabia, has been successfully carried out by the United Nations International Children's Emergency Fund and the World Health Organization with the cooperation of the government, according to a report submitted to WHO's regional office in Alexandria. The first phase of the campaign, directed by international personnel, has been completed. Between January and May more than 31,000 children were tested for tuberculosis and 8,000 vaccinated, and the international team trained national personnel to carry on BCG work. The campaign is now being conducted by local health authorities with the aid of supplies and equipment that will be provided for another year.

Penicillin Treatment for Venereal Disease in Ethiopia.—Penicillin treatments for syphilis were scheduled to be introduced in Addis Ababa in July by the Ethiopian Ministry of Public Health and the World Health Organization. The venereal disease control project will include serologic testing of the inhabitants of Addis Ababa and will demonstrate the efficacy of penicillin in curing syphilis and other venereal diseases. A fully equipped WHO team of three experts will be sent to work with an Ethiopian team under P. Serra, chief of the venereal disease center at Addis Ababa. Facilities for the work will be provided by the government at the Filoha and Tekla Haimanot Clinics. Arrangements have been made to conduct blood tests at the laboratories of the Pasteur Institute, formerly the Imperial Ethiopian Medical Research Institute of Addis Ababa. In addition to blood testing and treatment the project will include investigation of the distribution of venereal disease throughout the country.

EXAMINATIONS AND LICENSURE

BOARDS OF MEDICAL EXAMINERS

ALASKA:* *Examination.* Juneau. On application in other towns where there are board members. *Reciprocity.* On application. Sec., Dr. W. M. Whitehead, Box 140, Juneau.

CALIFORNIA: *Written.* Los Angeles, Aug. 18-21; Sacramento, Oct. 20-23. Application must be received at least two weeks prior to date of examination. *Oral for Reciprocity Applicants.* Los Angeles, Aug. 16; San Francisco, Nov. 8. Applicants are requested not to arrange to come to an oral examination until they receive notice from the Credentials Committee. *Oral and Clinical for Foreign Medical School Graduates.* Los Angeles, Aug. 17; San Francisco, Nov. 9. Sec., Dr. Frederick N. Scatena, 1020 N St., Sacramento.

GUAM: The Commission on Licensure will meet whenever a candidate appears or submits his credentials. Ex. Sec., Dr. Austin W. Matthis, Agana.

ILLINOIS: *Examination.* Chicago, Sept. 23-25. Supt. of Regis., Mr. Charles F. Kervin, Capitol Bldg., Springfield.

MISSOURI: *Reciprocity.* Jefferson City, July 27. Ex. Sec., Mr. John A. Hailey, Box 4, State Capitol Bldg., Jefferson City.

MONTANA: Helena, Oct. 6-8. Sec., Dr. S. A. Cooney, 214 Power Block, Helena.

NEVADA:* Carson City, Aug. 4. Sec., Dr. George H. Ross, 112 Curry St., Carson City.

NEW HAMPSHIRE: Concord, Sept. 10. Sec., Dr. John S. Wheeler, 107 State House, Concord.

NORTH CAROLINA: *Reciprocity.* Raleigh, Aug. 2. Sec., Dr. Joseph J. Combs, 419 Professional Bldg., Raleigh.

Oregon:* *Examination.* Portland, July 7-9. *Reciprocity.* Portland, July 25-26. Final date for filing application was June 16. Exec. Sec., Mr. Howard I. Bobbitt, 609 Failing Bldg., Portland.

Texas: *Reciprocity.* Fort Worth, Aug. 3. Sec., Dr. M. H. Crabb, 1714 Medical Arts Bldg., Fort Worth.

Wyoming: Cheyenne, Oct. 6. Sec., Dr. Franklin D. Yoder, State Office Bldg., Cheyenne.

BOARDS OF EXAMINERS IN THE BASIC SCIENCES

Alaska: *Examination.* On application. Juneau or other towns in Territory as decided by Board. *Reciprocity.* On application. Sec., Dr. C. Earl Albrecht, Box 1931, Juneau.

Colorado: *Examination.* Denver, Sept. 10-11. Sec., Dr. Esther B. Starks, 1459 Ogden St., Denver 18.

District of Columbia: *Examination.* Washington, Oct. 20-21. Sec., Dr. Daniel L. Seckinger, 4130 E. Municipal Bldg., Washington.

Michigan: *Examination.* Detroit and Ann Arbor, Oct. 10-11. Sec., Mrs. Anne Baker, 423 W. Michigan Ave., Lansing.

Nebraska: *Examination.* Omaha, Oct. 7-8. Director, Bureau of Examining Boards, Mr. Husted K. Watson, 1009 State Capitol Bldg., Lincoln.

Oklahoma: *Examination.* Oklahoma City, Sept. 13. Sec., Dr. Clinton Gallaher, 813 Braniff Bldg., Oklahoma City.

Oregon: *Examination.* Portland, Sept. 6 and Dec. 6. Sec., Dr. Charles D. Byrne, State Board of Higher Education, University of Oregon, Eugene.

Rhode Island: *Examination.* Providence, Aug. 13. Administrator of Professional Regulations, Mr. Thomas B. Casey, 366 State Office Bldg., Providence.

Texas: *Examination.* Austin, October. Sec., Brother Raphael Wilson, 407 Perry-Brooks Bldg., Austin.

Wisconsin: *Examination.* Madison, Sept. 13, Milwaukee, Dec. 6. Sec., Mr. W. H. Barber, 621 Ransom St., Ripon.

---

* Basic Science Certificate required.

MEETINGS

Alaska Territorial Medical Association, Anchorage, Aug. 21-23. Dr. William P. Blanton, P. O. Box 2569, Juneau, Secretary.

American Association of Obstetricians, Gynecologists and Abdominal Surgeons, The Homestead, Hot Springs, Va., Sept. 4-6. Dr. William F. Mengert, 2211 Oak Lawn Ave., Dallas, Texas, Secretary.

American Congress of Physical Medicine, Roosevelt Hotel, New York, Aug. 25-29. Dr. Frances Baker, One Tilton Ave., San Mateo, Calif., Secretary.

American Physiological Society, New Orleans, Sept. 4-6. Dr. E. F. Adolph, University of Rochester School of Medicine and Dentistry, Rochester, N. Y., Secretary.

Biological Photographic Association, Hotel New Yorker, New York, Sept. 10-12. Mr. Lloyd E. Varden, Pavelle Color, Inc., 533 W. 57th St., New York 19, Secretary.

Medical Society of Delaware, Rehoboth, Sept. 8-10. Dr. Andrew M. Gehret, 822 North American Bldg., Wilmington, Secretary.

National Medical Association, Chicago, Aug. 11-15. Dr. John T. Givens, 1108 Church St., Norfolk 10, Va., General Secretary.

Nevada State Medical Association, Reno, Aug. 21-23. Dr. William A. O'Brien III, 505 Chestnut St., Reno, Secretary.

New Hampshire Medical Society, Mt. Washington Hotel, Bretton Woods, Sept. 7-9. Dr. Deering G. Smith, 44 Chester St., Nashua, Secretary.

Post Graduate Medical Assembly of South Texas, Shamrock Hotel, Houston, July 21-23. Dr. C. A. Dwyer, 229 Medical Arts Bldg., Houston, Secretary.

Reno Surgical Society Conference, Reno, Nevada, Aug. 21-23. Dr. Olin C. Moulton, 130 N. Virginia St., Reno, Nevada, Chairman.

Rocky Mountain Radiological Society, Denver, Aug. 7-9. Dr. Maurice D. Frazer, 1037 Stuart Bldg., Lincoln, Neb., Secretary.

U. S. Chapter, International College of Surgeons, Conrad Hilton Hotel, Chicago, Sept. 2-5. Dr. Arnold S. Jackson, 1516 Lake Shore Drive, Chicago, Executive Secretary.

Utah State Medical Association, Salt Lake City, Sept. 4-6. Dr. T. C. Weggeland, 42 S. Fifth East St., Salt Lake City, Secretary.

Vermont State Medical Society, Mt. Washington Hotel, Bretton Woods, N. H., Sept. 7-9. Dr. James P. Hammond, 128 Merchants Row, Rutland, Secretary.

Washington State Medical Association, Olympic Hotel, Seattle, Sept. 13-17. Dr. Bruce Zimmerman, 338 White-Henry-Stuart Bldg., Seattle, Secretary.

West Virginia State Medical Association, The Greenbrier, White Sulphur Springs, July 24-26. Mr. Charles Lively, P. O. Box 1031, Charleston, Executive Secretary.

INTERNATIONAL

American Congress of Industrial Medicine, Rio de Janeiro, Brazil, Sept. 20-28. General Secretarial Office: Calle Arenales No. 981 Buenos Aires, Argentina.

Australasian Medical Congress, Melbourne Victoria, Australia, Aug. 22-30. Dr. C. H. Dickson, Medical Society Hall, 426 Albert St., East Melbourne, Victoria, Australia, General Secretary.

European Congress of Cardiology, University of London, Bloomsbury, W.C.1, England, Sept. 10-12. Dr. K. Shirley Smith, 35 Wimpole St., London, W.1, England, Secretary.

European Society of Cardiovascular Surgery, Strasbourg, France, Oct. 3-4. Sir James Learmonth, Department of Surgery, University New Buildings, Edinburgh 8, Scotland.

Interamerican Cardiological Congress, Buenos Aires, Argentina, Aug. 31-Sept. 7. Dr. Blas Moia, Larrea 1132, Buenos Aires, Argentina, Secretary-General.

Inter-American Congress of Public Health, Havana, Cuba, Sept. 27-Oct. 1. Pan-American Sanitary Bureau, 2001 Connecticut Ave., Washington, D. C.

Inter-American Congress of Radiology, Mexico City, Mexico, Nov. 2-8. Dr. Guido Torres Martinez, Marsella No. 11, Mexico, D.F., Secretary-General.

International Congress of Anthropology and Ethnology, Vienna, Austria, Sept. 1-8. For information write: Secretaries, Royal Anthropological Institute, 52 Upper Bedford Place, London, W.C.1, England.

International Congress of Biochemistry, Paris, France, July 21-27. Prof. Jean Courtois, 4, Avenue de l'Observatoire, Paris 6^{e}, France, Secretary.

International Congress of Dermatology and Syphilology, London, England, July 21-26. Dr. Gordon B. Mitchell-Heggs, 5, Lisle St., London, W.C.2, England, General Secretary.

International Congress on Diseases of the Chest, Rio de Janeiro, Brazil, Aug. 24-30. Mr. Murray Kornfeld, 112 East Chestnut St., Chicago 11, Illinois, Executive Secretary.

International Congress of Haematology, Mar del Plata, Argentina, Sept. 21-26. Dr. Carlos Reussi, Anchorena 1710, Buenos Aires, Argentina, Secretary.

International Congress of the History of Medicine, Nice-Cannes, France, and Monaco, Sept. 8-14. Dr. F. A. Sondervorst, 124 Avenue des Allies, Louvain, Belgium, Secretary-General.

International Congress on Hydatid Disease, Santiago, Chile, Nov. 21-24. Organizing Committee, P. O. Box 9183, Santiago, Chile.

International Congress of Internal Medicine, Friends House, London, N.W.1, Eng. Sept. 15-18. Sir Harold Boldero, 12 Pall Mall East, London, S.W.1, England, Secretary.

International Congress of Medical Press, Venice, Italy, Oct. 4-5. Dr. Bruno de Biasio, S. Marco 4646, Venice, Italy, Secretary.

International Congress on Medical Records, London, England, Sept. 7-12. Miss Gwen Perkins, 120 C Street S.E., Washington, D. C., Chairman.

International Congress of Military Medicine and Pharmacy, Montevideo, Uruguay, March 1-7. Dirreccion General del Servico de Sanitad Militar, 8 de Octubre y Mariano Moreno, Montevideo, Uruguay, Secretariat of the Congress.

International Congress on Neuropathology, Rome, Italy, Sept. 8-13. Dr. Armando Ferraro, 722 W. 168th St., New York, N. Y., U. S. A., Secretary General.

International Congress of Otorhinolaryngology, Amsterdam, Netherlands, June 8-15, 1953. Dr. W. H. Struben, J. J. Viottastraat 1, Amsterdam, Netherlands, Secretary.

International Congress of Urology, The Waldorf-Astoria, New York, N. Y., U. S. A., Sept. 15-18. Dr. John A. Taylor, 2 East 54th St., New York, N. Y., U. S. A., Secretary-General.

International Hospital Congress, London, England, May 25-30, 1953. Capt. J. E. Stone, 10 Old Jewry, London, EC2, England, Hon. Secretary.

International Union Against Tuberculosis, Rio de Janeiro, Brazil, Aug. 24-27. Prof. Etienne Bernard, 66 Blvd. St. Michel, Paris 6e, France, Secretary-General.

Medical Women's International Association, Vichy, France, Sept. 12-16. Dr. Margaret M. Wurts, 27 East Wellesley Road, Montclair, N. J., U. S. A., National Secretary.

Neuroradiologic Symposium, Stockholm, Sweden, Sept. 17-20. Docent Ake Lindbom, Symposium Neuroradiologicum, Serafimerlasarettet, Stockholm K., Sweden, Secretary.

World Congress of Jewish Physicians, Jerusalem, Israel, Aug. 10-14. Secretariat: % Israel Medical Association, Rehov Mesilat Yesharim, Beth Kovatz, Jerusalem, Israel.

World Congress of Medicine, Montecatini, Italy, Oct. 16-18. Secretariat: Corso Trieste, 65, Rome, Italy.

World Federation of Mental Health, Brussels, Belgium, Aug. 25-Sept. 1. Dr. J. R. Rees, 19 Manchester St., London, W.1, England, Secretary.

World Medical Association, Athens, Greece, Oct. 12-16. Dr. Louis H. Bauer, 2 East 103d St., New York 29, N. Y., Secretary General.

DEATHS

Wood, Neal Naramore ⊕ Santa Clara, Calif.; born in Lamar, Mo., July 24, 1884; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1908; Army Medical School, 1912; commissioned in the regular Army Medical Corps and later resigned; served during World War I; formerly professor of public health (hospital administration) at College of Medical Evangelists, Loma Linda and Los Angeles, and on the faculty of his alma mater; formerly health director of Charlevoix, Emmet, Otsego, and Antrim counties in Michigan and in charge of the Bay County (Mich.) department of health; at one time superintendent of the Los Angeles County General Hospital in Los Angeles, and director of Starling-Loving University Hospital in Columbus, Ohio, and Hillman Hospital in Birmingham, Ala.; died in Agnews State Hospital in Agnew March 25, aged 67, of chronic myocarditis and arteriosclerosis.

Spangler, Davis ⊕ Dallas, Texas; born in Bonham, Texas, Sept. 30, 1892; University of Texas School of Medicine, Galveston, 1913; clinical assistant professor of radiology, Southwestern Medical School of the University of Texas; specialist certified by the American Board of Radiology; member of the Radiological Society of North America of which he was vice-president, American Roentgen Ray Society, and the American College of Radiology; past president of the Dallas County Medical Society; served in France during World War I; during World War II county chairman of procurement and assignment of medical personnel for the military services; affiliated with Texas Scottish Rite Hospital for Crippled Children, Children's Medical Center and Medical Arts Hospital; died in Gaston Hospital April 13, aged 59, of rheumatic heart disease and cononary sclerosis.

Booth, Thomas Fagan ⊕ Pulaski, Tenn.; Vanderbilt University School of Medicine, Nashville, Tenn., 1926; member of the American Academy of General Practice; died in Baptist Hospital, Knoxville, April 9, aged 50, of cerebral hemorrhage.

Brookie, Roger William ⊕ Flora, Ind.; Northwestern University Medical School, Chicago, 1908; served during World Wars I and II; died in Tifton, Ga., April 22, aged 69, of heart failure.

Caseley, Walter Norris, Long Beach, Calif.; Central Medical College of St. Joseph, Mo., 1895; affiliated with Seaside Hospital, where he died April 7, aged 78.

Cornell, Earl Hamilton, Oakland, Calif.; University of California Medical School, San Francisco, 1913; physician for the Matson Navigation Company for many years; died in Yreka April 23, aged 64, as the result of an automobile accident.

Harrod, George ⊕ Conway, Ark. (licensed in Arkansas in 1903); died April 11, aged 82, of heart disease.

Hawkins, Norman Louis ⊕ Watertown, N. Y.; Columbia University College of Physicians and Surgeons, New York, 1902; specialist certified by the American Board of Pediatrics; member of the American Academy of Pediatrics; affiliated with Good Samaritan and Mercy hospitals; died recently, aged 70, of cerebral embolism, arteriosclerotic heart disease, and chronic cholecystitis.

Hays, Thomas Walden, Cincinnati; Medical College of Ohio, Cincinnati, 1888; for many years on the staff of St. Mary's Hospital; died in St. Francis Hospital April 3, aged 88, of arteriosclerotic heart disease.

Henry, Taylor H., Columbus, Miss.; Memphis (Tenn.) Hospital Medical College, 1899; state senator; died in Jackson March 23, aged 76.

Herff, Adolph ⊕ Boerne, Texas; Jefferson Medical College of Philadelphia, 1880; fellow of the American College of Surgeons; formerly practiced in San Antonio, where he was affiliated with Santa Rosa Hospital; died recently, aged 93, of cancer.

Hoare, Harry James, Los Angeles; College of Physicians and Surgeons, Medical Department of the University of Southern California, Los Angeles, 1910; died recently, aged 68.

Hochwalt, Gustav A., Dayton, Ohio; Starling Medical College, Columbus, 1895; for many years affiliated with Miami Valley Hospital and St. Elizabeth Hospital, where he died recently, aged 79, of cardiovascular renal disease.

Jacobi, Felix ⊕ New York City; Kaiser-Wilhelms-Universität Medizinische Fakultät, Strasbourg, Germany, 1908; died April 1, aged 69, of leukemia.

Jacobs, Gustave Edgar ⊕ St. Louis; St. Louis College of Physicians and Surgeons, 1915; member of the American Academy of General Practice; died April 5, aged 68, of heart disease.

Kenoyer, William Ray ⊕ Hugoton, Kan.; University of Kansas School of Medicine, Kansas City, 1931; served during World Wars I and II; county coroner; died April 16, aged 54, of coronary heart disease.

Klaveness, Eivind, St. Paul; Kongelige Frederiks Universitat Medizinske Fakultet, Oslo, Norway, 1897; died April 10, aged 81, of coronary sclerosis.

Lee, Edwin Henry ⊕ Tuskegee, Ala.; Howard University College of Medicine, Washington, D. C., 1915; affiliated with Veterans Administration Hospital; died recently, aged 65, of melanosarcoma of the liver.

Leicht, Phillip ⊕ Lakemills, Wis.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1907; an Associate Fellow of the American Medical Association; served during World War I; died in Milwaukee recently, aged 69, of abscess of the lung and bronchopneumonia.

Leonard, Isaac Edward ⊕ Atlantic City, N. J.; College of Physicians and Surgeons, Boston, 1899; also a graduate in pharmacy; formerly member of the board of education; died March 31, aged 89, of cerebral thrombosis.

Levin, Arthur Aaron, Brooklyn; University and Bellevue Hospital Medical College, New York, 1921; died recently, aged 53.

Lowry, Casper Franklin, Dover, Fla.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1910; died March 30, aged 68, of carcinoma of the lung and liver.

McCarthy, Michael Joseph, Philadelphia; Medico-Chirurgical College of Philadelphia, 1916; died recently, aged 60, of carcinoma of the laryngopharynx.

McDonald, George Oliver ⊕ Detroit; University of Toronto Faculty of Medicine, Toronto, Ontario, Canada, 1920; died in Thamesford, Ontario, April 8, aged 60, of coronary thrombosis.

McLean, John Allan Cameron ⊕ Somerville, Mass.; Harvard Medical School, Boston, 1904; an Associate Fellow of the American Medical Association; served during World War I; veteran of the Spanish-American War; member of the senior consulting staff of Somerville Hospital, where he died April 8, aged 72, of cerebral hemorrhage.

McMillan, Robert C. ⊕ Monmouth, Ill.; the Hahnemann Medical College and Hospital, Chicago, 1905; served as city health officer; formerly on the staff of the Monmouth Hospital; died in Moline April 13, aged 89, of cerebral arteriosclerosis.

Meckstroth, Henry Louis ⊕ Mansfield, Ohio; Jefferson Medical College of Philadelphia, 1908; served during World War I; died March 12, aged 69.

Miller, Burton Jonathan, Massillon, Ohio; Homeopathic Hospital College, Cleveland, 1887; died March 18, aged 88.

Nanninga, John Benjamin ⊕ Newton, Kan.; Rush Medical College, Chicago, 1928; certified by the National Board of Medical Examiners; affiliated with Bethel Deaconess Hospital; died April 18, aged 53, of coronary occlusion.

⊕ Indicates Member of the American Medical Association.

Panaro, Peter Thomas ⊕ New York; University of Arkansas School of Medicine, Little Rock, 1928; died Feb. 7, aged 51.

Parkhurst, Jane Hunting Sutherland, San Francisco; New York Medical College and Hospital for Women, Homeopathic, New York, 1902; at one time health officer of Burlingame; served on the staff of Hahnemann Hospital, where she died April 18, aged 85, of coronary disease.

Parnell, Henry Elliott ⊕ Perrine, Fla.; Kentucky School of Medicine, Louisville, 1908; served overseas during World War I; died in Lake City April 20, aged 70.

Pectol, Charles F. ⊕ Spencer, Ind.; Louisville (Ky.) Medical College, 1898; for many years county health officer; died in St. Vincent's Hospital, Indianapolis, April 7, aged 85, of cerebral hemorrhage.

Ramstad, N. Oliver ⊕ Bismarck, N. D.; University of Minnesota College of Medicine and Surgery, Minneapolis, 1899; past president of the North Dakota State Medical Association; member of the founders group of the American Board of Surgery; died in St. Petersburg, Fla., recently, aged 76, of arteriosclerosis.

Ries, Gay K. Durbin, Wilmington, Del.; Woman's Medical College of the New York Infirmary for Women and Children, New York, 1892; at one time practiced in Chicago; died recently, aged 86, of myocardial infarction.

Rigby, Owen Compton ⊕ Shreveport, La.; Tulane University of Louisiana School of Medicine, New Orleans, 1920; member of the Southeastern Surgical Congress; fellow of the American College of Surgeons; on the staff of the Tri-State Hospital and North Louisiana Sanitarium; died recently, aged 63.

Sandifer, Vollie LaFayette ⊕ Logansport, La.; Atlanta Medical College, 1915; died recently, aged 62.

Scheer, George Henry, Sheboygan, Wis.; Rush Medical College, Chicago, 1903; served with the U. S. Public Health Service; affiliated with Sheboygan Memorial Hospital and St. Nicholas Hospital, where he died April 7, aged 74, of coronary thrombosis.

Schellhamer, William Heinly ⊕ York, Pa.; Medico-Chirurgical College of Philadelphia, 1916; member of the Industrial Medical Association; served during World War I; on the staff of York Hospital; died March 21, aged 59.

cherrer, Frederick William Jr. ⊕ St. Louis; St. Louis University School of Medicine, 1928; specialist certified by the American Board of Otolaryngology; on the staffs of the Barnes and Evangelical Deaconess hospitals; died April 7, aged 49, of cerebral hemorrhage.

Schindler, Hans Joachim ⊕ New York; Kaiser-Wilhelms-Universität Medizinische Fakultät, Strasbourg, Germany, 1905; died April 21, aged 70, of carcinoma.

Seville, David Walter ⊕ Bellevue, Pa.; Western Pennsylvania Medical College, Pittsburgh, 1900; on the staff of the Suburban General Hospital, where he died April 4, aged 82.

Seymour, Charles R., Binghamton, N. Y.; Albany (N. Y.) Medical College, 1892; member of the American Medical Association; twice president of the Broome County Medical Society; served during World War I; for many years connected with the National Guard; in 1944 was given a citation for distinguished service by the Alumni Association of Albany Medical College; on the staff of the Binghamton City Hospital, where he died April 28, aged 82, of coronary thrombosis.

Shaw, Manning Franklin, Omega, Ga.; University of Georgia Medical Department, Augusta, 1912; on the staff of the Vereen Memorial Hospital in Moultrie; died in John D. Archbold Memorial Hospital, Thomasville, April 2, aged 65, of carcinoma of the prostate.

Sheller, William Owen ⊕ Los Angeles; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1902; an Associate Fellow of the American Medical Association; affiliated with St. John's and Santa Monica hospitals in Santa Monica, and Culver City (Calif.) Hospital; died April 23, aged 78, of rupture of a dissecting aortic aneurysm, hypertension, and arteriosclerosis.

Sisk, Crete Nixon, Morganton, N. C.; University of Nashville Medical Department, 1905; district health officer; served as health officer of Vance County; died recently, aged 69, presumably of cardiovascular crisis.

Smith, Elisha Baker ⊕ Birmingham, Ala.; Birmingham Medical College, 1912; died recently, aged 64, of coronary occlusion and cerebral accident.

Smith, Frank Arthur ⊕ Westbrook, Maine; Medical School of Maine, Portland, 1915; died recently, aged 69, of cerebral hemorrhage and hypertension.

Smith, Robert Gillespie, Fayetteville, Ark.; Ohio State University College of Medicine, Columbus, 1940; served during World War II; died March 20, aged 40.

Smithwick, Marsena Parker ⊕ Boston; Harvard Medical School, Boston, 1895; formerly affiliated with the Boston City Hospital; medical inspector for the public schools; died March 30, aged 84.

Stephens, John Henry, Hendersonville, Tenn.; University of Nashville Medical Department, 1901; died recently, aged 81, of injuries received in an automobile accident.

Sweeney, John Joseph ⊕ Upper Darby, Pa.; Medico-Chirurgical College of Philadelphia, 1914; formerly trustee and councilor, Second Councilor District, Medical Society of the State of Pennsylvania; past president of the Delaware County Medical Society; affiliated with Misericordia, St. Agnes, and St. Joseph's hospitals, all in Philadelphia, and the Fitzgerald-Mercy Hospital in Darby, where he died April 18, aged 62, of gastric and duodenal ulcer and intestinal obstruction.

Talbot, Benjamin H., Ruston, La.; Medical Department of Tulane University of Louisiana, New Orleans, 1893; died April 27, aged 81, of cardiovascular accident.

Terrell, Leland Leslie, Woodbine, Ky.; University of Louisville (Ky.) Medical Department, 1910; for many years member of the school board; died in Lenoir City, Tenn., April 8, aged 62, of diabetes mellitus.

Thomas, Deleon Hale, French Camp, Miss. (licensed in Mississippi in 1911); died in Baptist Hospital, Jackson, April 2, aged 68.

Waller, Amos Orville ⊕ Eugene, Ore.; College of Physicians and Surgeons of San Francisco, 1916; past president of the Lane County Medical Society; served during World War I; formerly member of the state legislature; affiliated with Sacred Heart General Hospital, where he was chief of staff; died April 16, aged 69, of a heart attack.

Watson, James ⊕ Cleveland; Northwestern University Medical School, Chicago, 1925; specialist certified by the American Board of Psychiatry and Neurology; member of the American Psychosomatic Society, American Psychiatric Association and the Association for Research in Nervous and Mental Diseases; formerly chief neuropsychiatrist, Regional Office, Veterans Administration; served during World War II; an ordained minister; died April 27, aged 68, of myocardial infarction and arteriosclerosis.

Webb, William S. ⊕ Wheeling, W. Va.; College of Physicians and Surgeons, Baltimore, 1904; affiliated with Ohio Valley General Hospital and Wheeling Hospital, where he died April 11, aged 73, of acute suppurative pancreatitis.

Weighart, Joseph Benjamin ⊕ New York; Cornell University Medical College, 1901; for many years on the staff of French Hospital; died April 27, aged 79, of a heart attack.

Whitaker, Darel Wesley, Batesville, Miss.; University of Tennessee College of Medicine, Memphis, 1925; died March 22, aged 59, of coronary thrombosis.

Williams, Owen Hassell ⊕ Savannah, Tenn.; University of Nashville Medical Department, 1907; died March 22, aged 71, of a heart attack.

Wilson, Middleton Ford, New Orleans; Medical Department of Tulane University of Louisiana, New Orleans, 1903; died in Southern Baptist Hospital April 13, aged 73, of carcinoma.

Woltz, John Louis, Mount Airy, N. C.; Southern Medical College, Atlanta, 1897; died March 21, aged 79, of arteriosclerotic heart disease.

GOVERNMENT SERVICES

ARMY

Medical Service Celebrates 177th Anniversary.—The Army Medical Service will celebrate its 177th anniversary on July 27. From the small group of doctors and assistants organized as a medical department by the Continental Congress in 1775 at the behest of General George Washington, the Army Medical Service has grown to the largest military medical service in existence. Whether in combat or out, Army medical personnel are dedicated to the task of safeguarding and restoring the health of the individual soldier, and the combined efforts of its physicians, nurses, medical specialists, and enlisted men and women have created the healthiest combat force in history.

Society Election in Japan.—Col. George M. Powell is the newly-elected president of the Southern Honshu Medical Society, chosen during a society meeting at the 279th General Hospital. The colonel is chief of medical service at Osaka Army Hospital. Col. Sterrett E. Dietrich, commanding officer of the Kyoto Army Hospital, was elected first vice-president; Lieut. Col. John L. Mothershead, commanding officer, Nara Station Hospital, second vice-president; Major Carl Meeks, orthopedic clinic chief, 382nd General Hospital, secretary; and Lieut. Col. Edward P. Shannon, professional service chief, 279th General Hospital, treasurer.

ATOMIC ENERGY COMMISSION

Oak Ridge Institute Renews Contract.—The Atomic Energy Commission and the Oak Ridge Institute of Nuclear Studies, Inc., have signed a contract for the institute to continue its operation of certain programs for the AEC for another five years. This nonprofit educational corporation is composed of 30 member universities in the South and Southwest. The president of the institute is Dr. Paul M. Gross, vice-president of Duke University. The chief resident officer is Dr. William G. Pollard, executive director. Founded in 1946, with 14 charter member universities, the institute uses some of the unique atomic energy facilities in Oak Ridge to carry out research and training in the nuclear sciences.

The basic purposes of the institute are (1) to stimulate cooperation between the government and participating universities, in undertaking fundamental research in atomic energy; (2) to foster increased opportunities and improved programs of graduate study and education in nuclear energy in educational institutions of this region; (3) to aid in acquisition and training of scientific personnel; and (4) to use Oak Ridge's unique facilities for graduate research and instruction.

Specialized programs carried on by the institute include the conduct of courses in the handling of radioactive isotopes; the operation of a long-range research program on the treatment of malignant diseases; and the operation of the American Museum of Atomic Energy, together with its traveling exhibits. The institute also sponsors programs cooperatively with the Oak Ridge National Laboratory, which is operated by Carbide and Carbon Chemicals Co., and administers the AEC-sponsored fellowship program on a nationwide basis.

Member universities of the Institute are: Agricultural and Mechanical College of Texas, Alabama Polytechnic Institute, Catholic University of America, Clemson Agricultural College, Duke University, Emory University, Forida State University, Georgia Institute of Technology, Louisiana State University, Mississippi State College, North Carolina State College, Rice Institute, Tulane University of Louisiana, Vanderbilt University, Virginia Polytechnic Institute, University of Alabama, University of Arkansas, University of Florida, University of Georgia, University of Kentucky, University of Louisville, University of Maryland, University of Mississippi, University of North Carolina, University of South Carolina, University of Oklahoma, University of Puerto Rico, University of Tennessee, University of Texas, and University of Virginia.

DEPARTMENT OF DEFENSE

The Armed Forces Medical Library.—The appointment of Lieut. Col. Frank B. Rogers (MC) as director of the recently established Armed Forces Medical Library has been announced. The library, the largest institution of its kind in the world, will serve as a central medical library for the Army, Navy, and Air Force and as a national library for medicine and related sciences. The library's extensive facilities will also be available to medical research and development contractors, other governmental agencies, and civilian physicians and medical scientists of all countries.

Formerly known as the Army Medical Library, the newly-named establishment gained an international reputation through the publication of its Index-Catalogue, the most extensive bibliography of medicine in existence. In 1950 the decision was made to phase out the remaining activities of this monumental bibliography and to substitute for it a monthly publication, the Current List of Medical Literature. This publication enables the library to maintain an up-to-date bibliography of the world's medical literature.

Functioning mostly on a mail order basis, the library receives requests for books, references, and other material from all over the world. During the fiscal year 1951, more than 29,700 books were lent to borrowers in the United States. During that same period requests for information numbered 55,900. The library is able to furnish microfilms or photostatic copies of desired material for a very nominal sum. Also available are microfilm copies of publications which may be obtained on a loan basis. The photoduplication service received 56,000 orders requiring over 1,500,000 pages of film and print reproductions during the fiscal year 1951.

In 1942 because of space limitations, it became necessary for the library to move part of its collection to Cleveland, where a history of medicine division was established at the Allen Memorial Medical Library on the campus of Western Reserve University. To this location was transferred all of the medical literature written prior to 1850. The art section of the library has more than 21,000 pictures and almost 13,000 negatives.

PUBLIC HEALTH SERVICE

Fetal Deaths.—The 70,584 fetal deaths at the gestational age of 20 weeks or more registered in the United States for 1949 is the lowest number ever recorded, according to a recent report by the National Office of Vital Statistics. The fetal death ratio based on this figure is 19.8 per 1,000 live births. Although the 1949 figure is the lowest on record for the United States, it fails by a large margin as a measure of the pregnancy loss problem. The U. S. National Committee on Vital and Health Statistics has estimated that if fetal deaths of all gestational ages were recorded, the annual number in this country would be about half a million. However, until 1950, the definition of a fetal death (stillbirth) for registration purposes related exclusively to fetuses reaching the 20th week of gestation, and the definition and reporting requirements in many states varied from the national recommendation.

In 1950, the Third World Health Assembly recommended uniform adoption of the following, broader definition: "Fetal death is death prior to the complete expulsion or extraction from its mother of a product of conception, irrespective of the duration of pregnancy; the death is indicated by the fact that after such separation, the fetus does not breathe or show any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles." The new definition has been adopted by numerous national organizations and during 1951 several states took action to place the definition in effect.

FOREIGN LETTERS

CHILE

Ten Years of Preventive Medicine.—The law concerning preventive medicine came into being in 1938 and applies to all workers who are included under the social security law. It consists of an annual examination, including serologic tests for syphilis, a chest roentgenogram, and a cardiovascular check-up (blood pressure and auscultation). If the person is suspected of having either syphilis, tuberculosis, or cardiovascular disease, he is sent for further investigation to a specialist. Free treatment and rest are provided if his condition can be improved. During the period of treatment the patient receives his usual salary, but it is paid to him by the government from a fund into which the employer pays 1% of the employee's salary. The study presented by Prof. B. Viel refers to the examination of 97,255 white collar employees of Santiago examined during the 10 years 1938-1947.

Syphilis.—Of the 97,255 persons examined the prevalency of persons with syphilis was 5%, there being 3 to 4 times more men afflicted than women. During the last 10 years the prevalence decreased by 53% in men and by 83% in women. The incidence, which was 1%, decreased by 50%. All this seems to prove that the number of cases of syphilis to be seen in the future will be fewer and fewer. The treatment did not produce epidemiological changes because in no case was the contact brought under examination. The drugs used were the arsenic-bismuth combinations, which are very antiquated. Now penicillin has radically changed the problem. The conclusion drawn by the author is that there is no sense in making a mass serologic test of the population partly because the vast majority of cases found in this manner are of the noncontagious type of syphilis and also because the number of syphilis victims is decreasing day by day.

Tuberculosis.—Of the persons examined for the first time between the years 1938 and 1947, 19% were sent to specialists in bronchopulmonary disease. The prevalency of tuberculosis was 5% and has decreased during the 10 years by 45%. The incidence was 1.5%, and its decrease is even greater than that of prevalency. Thus between the years 1943 and 1947 it dropped by 64%. During the 10 years of work, 4,741 persons were diagnosed as suffering from tuberculosis. Of these, 82% were diagnosed during their first check-up, 12.2% in the annual control examinations of persons previously considered as healthy, 2.9% in the annual check-up of inactive tuberculosis patients, and 3.1% during annual examination of patients who did not want to consult the specialist after their first check-up. Not taking into consideration this last group we may safely say that the most productive group in regard to the finding of tuberculosis patients, irrespective of the nature of their lesions, is that of the so-called inactive tuberculosis patients, followed by persons examined for the first time, and lastly by the annual check-up of the group of healthy persons. Of the 4,741 patients 39.4% had minimal tuberculous lesions, 34.5% moderate lesions, 9% advanced lesions, 8.6% extrapulmonary tuberculosis, and 8.5% pleurisy. Of the total of 4,741 patients 90.2% benefited from the law of preventive medicine. Of the 395 cases of pleurisy 96.4% were considered healthy after treatment, and 3.6% were incurable. Less than nine months of rest were necessary in 50%. Of the patients with minimal tuberculous lesions 97% were cured and 50% had less than eight months' rest. Of the 1,612 cases of moderate lesions 71% were cured. Analyzing these results the author concludes that the recuperation of the patient is better when the lesion is smaller and those with a negative bacilloscopy have a better prognosis than those with a positive bacilloscopy.

If we compare the percentage of persons who died after 10 years after having been treated with that of persons who were considered incurable from the very start we see that the mortality in the first group is 10% and in the second group 60%. The author points out that the surviving 40% of the incurable group presents a very serious problem in dissemination of the disease. Regarding the treatment, 4,276 underwent sanatorial rest, surgery, or pneumotherapy. The author points out that the sanatorial treatment was done with no sense of epidemiology. Thus only 41.1% of patients with a positive bacilloscopy were sent to sanatoriums, and 15% with a negative bacilloscopy and 20% in whom no search for Koch's bacillus was made were sent to sanatoriums. The author points out that, since there is such a shortage of beds, these must be used in a more practical manner and since those patients with a positive bacilloscopy are twice as dangerous from the point of view of contagion than those with a negative bacilloscopy the former group must be given preference for sanatorial rest.

Cardiovascular Diseases.—Of the patients examined 18.8% were sent to a specialist of cardiovascular diseases. The prevalency of cardiovascular disease was 5.8% and was higher than tuberculosis and syphilis. Whereas the latter two decreased considerably during the 10 years of observation the incidence of cardiovascular disease only showed a small drop. The incidence is 2%. At their first examination 77% of the total number of cases were diagnosed. The yearly examination of the so-called healthy group gave 18% and that of the suspected group gave the final 5%. Regarding the etiological diagnosis, hypertension accounted for 70% of the patients, including arteriosclerosis 35.8%, valvular lesions 8.2%, cardiovascular syphilitic lesions 6.6%, and myocardial infarctions 2.5%; dysthyroidism 1%; polyarticular rheumatism 1.6%; congenital heart disease 0.4%; and chronic pulmonary heart disease 0.3%.

The patients were catalogued into four groups according to their functional capacity: (1) those who were asymptomatic, (2) those who presented discrete symptoms but were still able to work, (3) those whose working capacity was decreased, and (4) those who presented symptoms even at rest. During the first check-up 61% belonged to the first group, 20.3% to the second, 16.8% to the third, and 1.3% to the fourth. This brings us to the conclusion that only 36% of the patients require therapy. The author points out that 70% of the hypertensive group were asymptomatic, and 68.8% of the arteriosclerosis patients, 11.2% of the polyarticular rheumatism patients, 48.5% of nonsyphilitic valvular lesions patients, 63.8% of cardiovascular syphilitic patients, and 34% of the congenital heart disease patients did not have symptoms. The average age was 48 years in patients with heart disease, 36.7 years in the syphilitic group, and 30.3 years in the tuberculosis group. Of the 6,724 diagnosed cardiopaths 1,330 were given the benefits of the law. The percentage of those to enjoy the privileges of the law was smaller in the hypertensive and the arteriosclerotic group. This was to be expected because approximately 70% of these patients were asymptomatic. The law was applied to persons of the second and third group of the above-mentioned classification. The first was excluded because the patients were asymptomatic, and the fourth was excluded because the patients were considered as incurable. Thus 30% of the patients in the second group were receiving benefits from the law and 70% of the third group. Thus we see that 19% of all diagnosed cardiovascular patients received active therapy. Eighty per cent of the patients were improved, and therapy failed in only 10.7% of the cases; however, the high percentage of improvement obtained should not give a false impression of the situation because during these 10 years 209 patients who were considered improved presented on one or more occasions symptoms of relapse. Of this unimproved group 50% were hypertensive patients, 20% with valvular lesions, 10% arteriosclerosis, 7.5% myocardial infarctions, and 6.3% rheumatism; 0.6% were victims of hyperthyroidism; and 2% had other diseases.

The items in these letters are contributed by regular correspondents in the various foreign countries.

Mixed Pathologic Conditions.—1. Syphilis and tuberculosis: Of the patients with active syphilis 3.2% had some type of tubercular lesion. If we would apply the prevalency of tuberculosis to syphilitic patients to obtain the number of patients with tuberculosis that should exist theoretically among them we would find that the number is 222 cases whereas the 3.2% represents 170 cases. Thus a superficial analysis might induce us to the erroneous conclusion of saying that syphilis decreases the risk of tuberculosis. The author rejects this affirmation by saying that we cannot apply the prevalency of the tuberculosis group to the syphilitic group because of the difference of age in each case. 2. Syphilis and cardiovascular disease: In 443 cases the diagnosis was a syphilitic cardiovascular lesion. In case the prevalency of cardiovascular disease was to be applied to syphilitic patients the number of heart disease cases should have been 302, instead of the 443; however, there is a difference of 12 years between the average age of the syphilitic patient, who is much younger, and the cardiac patient. 3. Tuberculosis and cardiovascular disease: Only 1% of the tuberculous patients had heart disease. Thus if we were to apply the prevalency of cardiovascular disease to the tuberculosis group we could expect 270 instead of the 47 cases. The age factor again plays an important part in the correction of the prevalence. Concerning mixed pathologic conditions the author points out that, except in cases of syphilis and cardiovascular lesions, there are very few cases in which there are more than one diagnosis.

ISRAEL

Rabies Campaign.—Rabies incidence has been declining steadily in Israel since the start of the intensive nationwide campaign in October, 1950, according to Dr. Martin Kaplan, chief veterinary officer of the World Health Organization. The antirabies campaign, which is being waged with the assistance of WHO, includes a mass vaccination of dogs with a new egg-adapted vaccine (Flury strain), which has proved harmless to dogs and seems to give greater immunity of longer duration than other vaccines so far produced. The number of rabies cases in animals has dropped from an average of 100 a year before the start of the campaign to 10 (1 bull, 1 jackal, and 8 unvaccinated dogs) in the course of the past 15 months. All dogs in Israel have been registered, and vaccinated animals have received suitable identification. All stray dogs are being destroyed, while newborn animals are vaccinated when they reach 6 months of age. Vaccination is compulsory and free of charge.

Although it is still too early to determine to what extent vaccination alone has brought about the fall in rabies incidence in animals, Dr. Kaplan believes that the concentrated attack has played an important part in this matter. The drop is mirrored also in the decline in human deaths from rabies, which were none in 1951, whereas they numbered 20 between 1948 and 1950. In addition, the number of persons receiving Pasteur treatment following dog bites, which averaged 4,000 a year before the start of the campaign, has been cut to about one-half.

The campaign, which will be continued for the next few years, is expected to serve as a demonstration of the most effective method of rabies control and to provide a guide for other countries where the incidence of rabies is high. At the same time, it is yielding valuable information on the vaccine in use, such as the duration of immunity conferred by it under field conditions. Laboratory studies have shown that one inoculation of the vaccine gives adequate protection for a minimum period of two years. No revaccination of dogs in Israel will be practiced until there are indications that the immunity in vaccinated animals is beginning to wane.

Of equal importance is the greater feeling of security now being experienced among the population of the agricultural settlements. Israel's Veterinary Services, in cooperation with the Ministry of Health, are in charge of the campaign, while the necessary vaccine is being supplied at present through the WHO but will be produced in Israel in the future. WHO technical guidance is being provided through Dr. Kaplan. On his last visit, Dr. Kaplan was accompanied by Dr. Ernest S. Tierckel, who was loaned to WHO by the United States Public Health Service, where he directs rabies control activities. Dr. Tierckel has just completed a three month survey of rabies problems in Northern and Southern Rhodesia, Ceylon, Iraq, Greece, and Israel for WHO.

Rh Blood Types in Jews in Jerusalem.—J. Gurevitch and his associates from the Hebrew University-Hadassah Medical School, Jerusalem, have just finished a study of the Rh blood types of Jews living in Jerusalem.

Relatively few studies have been reported on the incidence of the Rh factor in Jews. In 1945 Gurevitch found in a select group of 400 women from different parts of the country that 15% were Rh-negative. It was obvious that this figure could not be considered as representative of a population selected at random. In later studies of a larger series, similar results were found for Ashkenasi (11% Rh-negative) and Sephardi groups (11.8% Rh-negative), whereas a much lower rate of persons with Rh-negative type blood was found among Yemenites (2.3% Rh-negative) and Kurdistani-Persians (1.5% Rh-negative). No instances of hemolytic disease of the newborn infant have been observed among 310 Yemenite and 1,739 Kurdistani-Persian Jewish women at the time of delivery.

A total of 1,335 samples of blood were tested for Rh types in Jews in Jerusalem with the aid of the following serums: anti-rh' (anti-C), anti-Rh_o (anti-D), and anti-rh" (anti-E). The subjects have been divided into three main groups: (1) Ashkenasi Jews, i. e., Jews of European descent, most of whom are from eastern European countries, (2) Sephardi Jews, descendants of Jews from medieval Spain, including Jews from North Africa (Algiers, Tunis, and Morocco), from southern Europe (Bulgaria and Greece), and an indigenous group from Israel, and (3) an Oriental group, including Jews from countries east of Israel (Iraq, Syria, and Afghanistan) but not from Persian and Kurdistani communities.

Percentage of Rh Types in Jerusalem Jews

Communal Group	No. of Persons	Types of Blood							
		Rh_1	Rh_2	Rh_1Rh_2	Rh_o	rh	rh'	rh"	rh'rh"
Ashkenasi	946	57.7	10.9	13.0	3.7	13.5	1.2	—	—
Sephardi	252	67.0	5.2	7.5	7.1	12.3	0.8	—	—
Oriental	137	64.3	10.2	7.3	4.4	13.1	0.7	—	—

In all three communal groups, the frequent occurrence of the Rh_1 (CDe) type was noteworthy, and this was especially true in the Sephardi group (67%) and among Oriental Jews (64.3%). Similar high percentages of Rh_1 type have been reported in Chinese and in Asiatic Indians. The rate of Rh_1Rh_2 among the Sephardi (7.5%) and Oriental Jews (7.3%) is low as compared with its rate in the Ashkenasi group of Jews and in other races.

The frequency of Rh-negatives (cde/cde) in this series was higher than that reported in previous studies and approached the rate for Rh-negatives reported for Europeans. It is noteworthy that the percentage of Rh-negative persons was similar in all three communal groups.

Convention of Psychiatrists in Haifa.—The Fifth National Convention of the Association of Neuropsychiatrists was held during May, 1952, in Haifa. It was disclosed at the gathering that, whereas the generally accepted figure of beds for mental cases is four for every thousand of the population, there are only 2,200 beds in Israel instead of the required 6,000. Generally speaking, the proportion of mental cases is higher in this country than in others, a fact that is accounted for by the large immigration (among which the proportion of mental cases is higher than average), the economic conditions that prevail locally, the overcrowding in dwellings, and the special difficulties encountered in new points of settlement, in *ma'baroth*, and in immigrants' camps. The hospitalization position for mental cases is catastrophic, a long time having to elapse before beds can be found for such patients. Suicides and acts of violence have been the result.

The convention voiced its demand for the establishment of work villages for chronic patients, labor camps for mental defectives, and a suitable home for epileptic patients, there being no such thing in the country at present.

Cardiovascular Research Unit.—The newly established cardiovascular research unit of the Hadassah University Hospital is headed by Dr. K. Braun. At a meeting of the Jerusalem Medical Association in February, 1952, the first report on the results of cardiac catheterization in patients with mitral stenosis was delivered. The pertinent findings were a rise in arteriovenous oxygen difference, a decrease in cardiac output and stroke index, a marked elevation of pulmonary arterial pressure, and some rise in right ventricular pressure. The competency of the right ventricle as an important factor in the production of paroxysmal pulmonary edema was emphasized.

At the meeting, Dr. A. M. Cohen of the Rothschild Hadassah Hospital reported on 18 patients with rheumatoid arthritis, bronchial asthma, and severe urticaria, who were treated by an intravenous drip of corticotropin. They found that a dosage of 1 to 3 mg. daily resulted in satisfactory clinical improvement. Unfavorable side-reactions were extremely few. The economical aspects of this treatment were stressed.

Dr. K. Braun discussed the effects of corticotropin on the pulmonary function in patients with bronchial asthma and obstructive emphysema treated by the above method. In the majority of patients, there was an improvement in the ventilatory functions of the lungs.

JAPAN

BCG Vaccination.—The annual tuberculosis death rate in Japan was around 200 per 100,000 population since 1900 showing a gradual decrease during the period 1925-1935. Although the highest peak was presented in the last war, the rate has decreased ever since 1947, dropping to 146.8 in 1950 and 111.1 in 1951.

The incidence of tuberculosis has been highest in the age group 15 to 29 as compared with that of the other groups. Almost all of these cases were of primary tuberculosis, proved by extensive studies clarifying the time of primary infection by means of repeated tuberculin testing on the nonreactors and the x-ray examination on the inverters. Indeed, nearly all of the pathological changes discovered through x-ray examination had appeared within one year after the positive inversion. As one of the chief measures for the prevention of the disease, stress was placed on the BCG vaccination of the tuberculin negative patients together with x-ray examination on the positive reactors.

The first attempt of BCG vaccination in Japan was made in 930 on the student nurses by Prof. Arao Imamura of the Osaka University. In 1938, the National Health Administration Committee of the Japan Association for the Promotion of Sciences organized an antituberculosis committee, the chief object of which was to make a study of the testing method of tuberculin reaction and of the use of BCG vaccination. The results of the five year research of this committee were published in April, 1943, proving the safety and efficacy of BCG vaccine.

In the year 1942, the welfare ministry recommended vaccination for all children applying for a position after leaving the primary school. The number of vaccinated persons increased year after year chiefly among such groups as the 7 to 25 year age group, workers in offices and plants, students, and families of tuberculous patients, totaling more than 7 million within 1948.

The Vaccination Law was put in force in July, 1949. 1. All of the tuberculin negative reactors under 30 years of age were to be included in the mass vaccination program. 2. Selection of the group to receive vaccination was to be done by tuberculin testing. Five toxic units of old tuberculin were injected intracutaneously into the flexor surface of the forearm, and after a 48 hour reading, BCG vaccination was made on the negative reactors with local redness less than 9 mm. in diameter. 3. Choice of groups for revaccination were to be made in the same way as the above. The number of vaccinated persons in 1950 was 13,941,855.

Because of its strong local reaction, ulceration and abscess, the subcutaneous injection was replaced in 1940 by the intracutaneous method: that is, intradermal injection of 0.1 ml. of the vaccine containing 0.4 mg. BCG per ml. Meanwhile, studies on scarification and multiple puncture methods are in progress. For the compulsory vaccination, the dried vaccine is to be employed, the products of which are carefully assayed to insure the safety and efficiency of the vaccine. The production of frozen-dried BCG vaccine is conducted by the Antituberculosis Association and its production plants located in Tokyo, Sendai, and Osaka. The total production of the vaccine will amount to 45 million doses annually.

PARIS

Treatment of Status Asthmaticus with ACTH and Cortisone.—Since 1950, Prof. Pasteur Valéry-Radot, C. L. Laroche, and their associates have treated with corticotropin (ACTH) and cortisone 33 patients with severe status asthmaticus at the medical clinic of the Broussais Hospital. The patients remained under observation for three months with the following results. Seventeen patients experienced a functional recovery lasting for some weeks; several of these, formerly invalids, were enabled to resume their occupations, and four had no crisis for two to eight months; but in six asthma reappeared after a remission of two months. Two complete failures were noted. In favorable cases, signs of improvement were observed from the second or third injection (12 to 24 hours). Expectoration diminished or disappeared in 22 patients. Eosinophils disappeared from the second day of treatment. The authors began the treatment with 75 to 100 mg. of corticotropin daily in divided doses for three to eight days, the dosage being then diminished. The treatment lasted for 3 to 23 days. In nine patients it was supplemented with a few injections of cortisone, without any noticeable change in the results. In eight patients multiple cures were undertaken. Studies with Thorn's test (fall of the eosinophil level) were made on 19 patients, and in 10 cases only was a fall of less than 50% obtained. There was no parallelism between the fall in eosinophils and the degree of therapeutic improvement; five patients with negative tests had excellent results with hormonal treatment. As regards toxic incidents, no outbreak of hypertension was noted, but six patients experienced hypotonia with marked asthenia; to prevent this a daily dose of from 1 to 2 gm. of potassium chloride was given during the treatment. In order to avoid infections (three pulmonary infections having been observed) the patients were given 1 gm. of aureomycin daily. Three deaths occurred in the course of treatment; in one case, the patient showed signs of cardiac deficiency, and the treatment, giving no results, was discontinued after 775 mg. had been administered; the other two patients died in severe asthma on the 27th and 34th day of treatment. The autopsy of one of them revealed an obstruction of the bronchi by secretion. The authors believe that, because of the possibility of an aggravation of the patients' condition following discontinuation of the treatment, medical supervision is required during the period called "hormonal weaning"; moreover, corticotropin and cortisone do not modify the evolution of the disease, being only symptomatic medications, and, immediately on the disappearance of critical phenomena, the patient should be given etiological treatment.

Hyaluronidase in the Toxicosis of Nurslings.—The value of intravenous perfusion in the treatment of toxicosis of nurslings is indisputable, but there are technical difficulties as well as the deadly risk of pulmonary edema, owing to the difficulty of regulating the drip. The substitution of subcutaneous for intravenous administration failed to produce the anticipated results because of the too slow resorption of the serum. Professor Turpin and his associates report that 250 cc. of an isotonic sodium chloride solution with hyaluronidase, injected subcutaneously, is absorbed within 10 minutes, without pain or distention of tissues. No dressing of hyaluronidase is used, and no incident is to be feared; there is only one contraindication to be noted: a serious skin infection that might be spread by hyaluronidase. In a 14-day-old child, treated by an intravenous perfusion, an extensive, hard subcutaneous infiltration, feeling like cardboard, appeared 24 hours after the perfusion in the lower limbs. Hyaluronidase was administered and, paradoxically, succeeded in bringing about the resorption of the edema, a reduction of weight, and an improvement in the general condition. It appears, therefore, that hyaluronidase has a general regulating action on the water exchanges between circulation and subcutaneous tissues, but this hypothesis requires verification. In the other cases, the authors observed that, with perfusion with hyaluronidase, definitive success was obtained after failure of intravenous transfusion. They believe that intravenous perfusion will become a useless technique, save in the exceptional cases of collapse, and that subcutaneous perfusion may be substituted.

TURKEY

Activities of Institute of Hygiene.—The Ankara Refik Saydam Institute of Hygiene was established in 1932 with an initial budget of 700,000 Turkish pounds from a special fund provided by the Ministry of Health and Social Assistance. The Rockefeller Foundation gave an $80,000 grant, which was spent on scientific equipment for the microbiology laboratory, the institute's first building; a plaque in the hall commemorates the philanthropic gift. At present the institute has three main buildings, in which are located departments of microbiology and chemistry, serology, virology, pharmacodynamics, departments that study vaccines and bacterial vaccines, antigens, and control of disease, and a kitchen for the study of nutrition. A vaccination center was opened in 1947.

The scientific staff of the institute consists of 16 specialist physicians, 4 veterinarians, 8 pharmaceutical chemists, 52 laboratory assistants, and 41 technicians.

In the *Bulletin of Hygiene and Experimental Biology*, Dr. Niyazi Musa Erzin and Dr. Orhan Hulusi Balkan reported on the activities of the institute from 1933 to 1949. Research concerned such public health problems as malaria, tuberculosis, trachoma, brucellosis, food-carried diseases, insects and insect-borne diseases, cholera, plague, and epidemics that may be introduced from neighboring countries. Until 1934, smallpox and bacterial vaccines and serums were prepared in Istanbul, and much was imported. They are now prepared at the institute, and during the last war Turkey sent cholera and plague vaccines as gifts to Egypt and Far-Eastern countries. Smallpox and bacteria vaccines are prepared in two departments, and BCG vaccine in a separate division. Cholera vaccine is obtained from five different strains received from Basra, Pasteur Institute, Marseilles, Egypt, and Istanbul. In 1947, because of the cholera epidemic in Egypt, 9,256 liters of vaccine were prepared and 8,295 liters were distributed; that year the vaccine contained 4 to 8 million germs in 1 cc., and the whole population in the south and in the southeastern provinces of Turkey was vaccinated. In 1948, 6,344 liters were prepared and 6,165 liters were distributed. Plague vaccine is prepared from six different strains, three of these are of old Turkish origin and three originated in Cairo. In 1947 the production was 4,416 liters, of which 3,854 were distributed. Polyvalent dysentery vaccine is prepared from Flexner's Y and E Turkish strains from Bucharest and the Pasteur Institute, and Shiga's R and S strains. Production in 1948 was 254 liters, of which 148 liters were distributed. Antimeningococcus vaccine is prepared from different Turkish strains. Since the introduction of penicillin and the sulfonamides its production has been reduced. Production in 1948 was 78 liters, and 73 liters were distributed. Combined typhoid and paratyphoid A and B vaccines are prepared for prophylactic use from selected strains of high antigenic value: 1 cc. contains 500 million typhoid and 250 million each of paratyphoid A and B strains. Production in 1948 was 2,856 liters, of which 2,100 liters were distributed. The production of antipneumococcus vaccine, types 1, 2, and 3, has been discontinued since 1941 in favor of penicillin and sulfonamides. From 1933 to 1948 BCG vaccine was prepared for oral administration only. The 1948 production was 14,800 doses, of which 7,309 doses were distributed. In 1948, 370 cc. of BCG vaccine for intracutaneous injections were prepared and distributed. The production of pertussis vaccine for prophylactic and therapeutic use was begun in a new laboratory during the latter months of 1948. It is prepared from Turkish and American strains and contains 1,000 million germs in 1 cc.; of 18 liters 3 liters were distributed. Staphylococcus vaccine is prepared from Staph. albus, Staph. aureus, and Staph. citreus; 22 liters were prepared in 1948, and 13 liters were distributed. Brucella vaccine is prepared for therapeutic use; it is obtained from more than 30 strains of Turkish and foreign origin. There are 1,000 million germs in 1 cc.; the vaccine is preserved in a dry state. Nine liters were prepared in 1948. Rabies vaccine for distribution to the 82 rabies centers is prepared according to the Semple method; it contains 5% brain tissue. That vaccine used at the institute vaccination station is prepared according to the Högyes method; 815 liters were prepared in 1948, of which 752 liters were distributed. Smallpox vaccine, after passage through two calves, is given an additional passage through a young donkey to strengthen the virus; the results have been very satisfactory. The smallpox vaccination law, which has been strictly enforced for 67 years, requires that vaccination be given during the first six months of life; it is required on entering schools and military or civil service, and in the event of an epidemic the whole population of that locality is revaccinated. In 1948 3 kg. of smallpox virus stock were prepared, and 26 million doses were distributed. In 1948 over a thousand liters of typhus vaccine were prepared according to the Cox method, and as a precautionary measure, a substantial amount was forwarded to the provincial health departments. The production of polyvalent bacteriophage for the use of summer diarrhea amounted to 730 liters; 536 liters were distributed. Very good results have been obtained with bacteriophage therapy combined with sulfaguanidine. Combined vaccines prepared during 1948 were: typhoid-tetanus 6,360 liters; diphtheria-tetanus 8,250 liters; typhoid-typhus 4,288 liters; typhoid-diphtheria 70 liters; plague-cholera 13 liters; typhoid-cholera-typhus 100 liters.

The preparation of toxins and anatoxins in Ankara was begun in 1934. For the preparation of diphtheria toxin and anatoxin, modified Müller-Wadsworth medium is used. There were 998 liters of diphtheria toxin and 864 liters of anatoxin prepared in 1948. Tetanus toxin and anatoxin is prepared from Pasteur Institute and Stick Dorne strain; 1,173 liters of toxin and 309 liters of anatoxin were prepared in 1948. Scarlatina toxin is prepared from hemolitic streptococci grown on media modified after the Ramon method; 139 liters were prepared in 1948.

Until 1933, serums were prepared in Istanbul, but much was imported; this is no longer necessary. The institute has no farm yet, but there are modern stables for serum and experimental animals. For the preparation of serums, horses and oxen are used; rams, young donkeys, and, sometimes, goats are used for rabies serum. The animals are quarantined for 20 days; they are tested for glanders and other diseases and are given tetanus inoculations. For the immunization toxins, anatoxins, germ emulsions, and stock strains are used. Tetanus serum for prophylactic use is prepared from oxen. It contains 1,000 and 3,000 units in 1 cc. For therapeutic use it is prepared from horses and contains 3,000 units, 10,000 units, and 30,000 units in 1 cc. There were 803 liters prepared in 1948. Diphtheria serum for prophylactic use is prepared from cattle and contains 1,000 units in 1 cc.; for therapeutic use it is prepared from horses, and it contains 3,000 units, 10,000 units, and 30,000 units in 1 cc.; 495 liters were prepared in 1948. The suspension of the organisms used for the immunization of horses from which polyvalent dysentery serum O is prepared contains 50% Shiga's bacillus. The serum of animals that have a minimum of 300 units in 1 cc. is regarded as satisfactory. The finished product contains 3,000 and 10,000 units in 1 cc.; 247 liters were prepared in 1948. Meningococcus serum is prepared from four foreign and Turkish strains; 176 liters were prepared in 1947. With the introduction of penicillin and sulfonamides, its production has been greatly reduced. Scarlet fever serum production was 58 liters in 1948, and polyvalent gangrene horse serum production was 331 liters. Scorpion antivenom is obtained from horses immunized with toxin of a scorpion found in Turkey; during 1945 to 1948, 55 liters of it were produced and almost all were distributed. Of 92 liters of rabies serum prepared in 1948, 16 liters were distributed. There were 934 liters of antianthrax serum prepared in 1948, of which 430 liters were distributed. Normal serum is of two kinds: one is for oral administration, the other for use in bacteriology laboratories; 134 liters were prepared in 1948.

Antigens prepared during 1948 included: Wassermann antigen (Organ) 11,600 cc.; Kahn antigen 8,260 cc.; Sachs antigen, 1933-1938, 8,500 cc., since 1938 discontinued; hemolitic serum 2,540 cc.; tuberculin 3,700 cc.; metylic antigen, bovine and human type, 2,570 cc.; diluted metylic antigen 3,330 cc.; and brucellargen for Brucella allergy 400 cc.

CORRESPONDENCE

GASTRIC LESIONS OF LOEFFLER'S SYNDROME

To the Editor:—I am very much interested in the article in The Journal, June 7, 1952, entitled "Gastric Lesion of Loeffler's Syndrome," reported by Ruzic, Dorsey, Huber, and Armstrong, and the findings at operation. I have seen the same lesions of the stomach with the comparable roentgenologic observations due to aureomycin. When therapy with the drug had been discontinued after a period of five to six weeks, the stomach completely returned to normal.

In one patient who came under my observation in July, 1949, and who had been given a copious dose of aureomycin, on roentgenologic examination edematous, pseudopolypoid diffused changes were found. These changes were so severe that we were considering gastrectomy. The gallbladder could not be visualized. X-ray examination was again performed on Aug. 9, 1949, and there was a complete disappearance of these pseudopolypoid changes of the stomach. The patient was operated on at the Johns Hopkins Hospital on Sept. 7, 1949. A cholecystectomy was performed, and the stomach gave no evidence of any lesion at operation. Gastroscopy one month before had revealed no evidence of any changes in the gastric mucosa, and this was verified on Aug. 9, 1949, by a repeat x-ray examination of the stomach.

Could not the lesion described in this so-called gastric lesion of Loeffler's syndrome be due to the changes that can occur in the gastrointestinal tract in association with the intake of aureomycin?

THE FUTURE OF OTOLARYNGOLOGY

To the Editor:—The editorial entitled "The Future of Otolaryngology," which appeared in the April 26 issue of The Journal, page 1508, was a true summary of the information now available in connection with otolaryngological practice today. However, more should have been said about meeting the challenge in spite of gloomy forecasts by some and bright predictions by others. It should be emphasized strongly that there always was, to a certain extent, the medical otolaryngologist whose chief interest lay in local rhinological and otological diseases (now allergic, psychosomatic, and dermatological) and the surgical otolaryngologist who quickly took up plastic surgery, bronchoesophagology, laryngoscopy, and even gastroscopy. Some mastered fenestrations, laryngeal surgery, neck dissection, esophageal surgery, and thyroid and cancer surgery; some also mastered ophthalmology and diseases of the chest.

Some of those who still practice the conventional field of otolaryngology, especially in smaller communities, call the surgeons "super-specialists," overlooking the greater opportunities available in our larger urban areas with the numerous postgraduate facilities.

I should like to call attention to part of a paper published by Dr. C. Gale in the *Eye, Ear, Nose and Throat Monthly* (30:601 [Nov.] 1951): "In the last few years otolaryngology has rapidly lost ground as a specialty. There are several reasons for this trend. The use of antibiotics and sulfonamide drugs has in great measure reduced the number of surgical procedures formerly commonplace. Surgeons who previously have boasted of using up a complete set of mastoid chisels every year, today rarely have the opportunity of doing a simple mastoidectomy. The general practitioner now armed with the newer antimicrobial agents has in large measure taken over the treatment of the acute and chronic infections of the sinuses, pharynx, and larynx. Even the fields of allergy, in all of its ramifications, have to a certain degree been taken from the specialist's domain by the introduction of the antihistamine drugs."

The above-mentioned author dwells on the reaction on the part of the otolaryngologist who was prompted to investigate and pick up all loose ends of his specialty. The first of the loose ends that became integrated into the specialty was plastic and reconstructive surgery. More important was the realization that the nose and throat surgeon could also be a head and neck surgeon, that there is nothing to prevent the otolaryngologist from doing cancer operations of the head and neck, thyroid surgery, or, for that matter, esophageal surgery. The importance of psychosomatic medicine is emphasized in the armamentarium of the specialty. Thus speaks an otolaryngologist in the largest city of our nation.

In conclusion, aside from expensive experimentation, especially in connection with private practice, there is no reason for anyone with surgical skill in certain techniques not to take up or advance in the various fields (unless handicapped by economic means). There is no reason for the nonsurgical physician to neglect such studies as allergy, audiology, physical medicine, and psychosomatic medicine. Besides, who prevents him from using the antibiotics and sulfonamide drugs? The various papers in the medical press and the excellent editorial of The Journal will do the problem more good than mere criticism or superficial suggestion.

THE CERVICAL CAP

To the Editor:—I question the advisability of publishing such inconclusive articles on the delicate field of infertility as "The Cervical Cap in the Treatment of Male Infertility" (*J. A. M. A.* **149:**427-431 [May 31] 1952). The authors state that the use of cervical cap is unquestionably indicated. I question this, for they do not adequately describe relative semen inadequacy and they do not adequately describe the sequence of events that preceded the use of the cap. They state that decreased metabolic function in one or both partners or other endocrine disturbances were corrected promptly. I beg to point out that these disorders are not corrected promptly. Furthermore, 15 cases of primary sterility with conception achieved in 10 (67%) hardly warrants publication, particularly when only 7 of their successes are true oligospermia as defined by Dr. John MacLeod of Cornell University.

The authors state that ovulatory time is determined by the vaginal smear technique. Again, this technique has not been proved to determine ovulatory time in any manner satisfactory, accurate, or informative. Many disagree as to the time of ovulation as determined by this technique. Further, there is no control over the patient's practices at home. In summary, I question advocating the cervical cap in the cases described.

PRESSURE TREATMENT OF MAXILLARY SINUSITIS

To the Editor:—Regarding the article "Pressure Treatment of Maxillary Sinusitis" by J. Mathews Robison in The Journal (page 436, May 31), I would like to say that this article is interesting and worth reading from the academic and philosophical viewpoint, but I doubt that it has any real practical application for the operating room.

BUREAU OF MEDICAL ECONOMIC RESEARCH

THE COST OF LIVING AND MEDICAL CARE PRICES

Frank G. Dickinson, Ph.D.

In the past year, the index of the prices of all items in the consumers' budget has risen almost twice as many points as the price of medical care. The Consumers' Price Index rose 13.7 points in 1951, and the index of medical care and drugs rose 7.1 points. In 1951, the Consumers' Price Index reached an all-time high of 185.6 while the index of the prices of medical care and drugs stood at 155.0. While the Consumers' Price Index has been considerably higher than the index of medical care prices in recent years, the spread between the two indexes became even more pronounced during 1951. The Consumers' Price Index had risen 86% since the base period, while the cost of medical care rose only 55%. In terms of purchasing power of the consumer dollar, medical care was 16% cheaper in 1951 than in 1935-1939, that is, 155.0 is 84% of 185.6.

As explained in our earlier publications,[1] the Consumers' Price Index, which is compiled by the U. S. Bureau of Labor Statistics, measures monthly the changes since 1935-1939 in the prices of fixed quantities of goods and services normally purchased by moderate-income families in large cities. The indexes of the medical care items are a small part of the entire index. This index is considered our best general measure of the purchasing power of the consumer dollar and is widely used to determine wages in labor negotiations.

How have the prices of the individual medical care items behaved? As shown in the accompanying table, the index of medical care excluding drugs was 160.9 in 1951 and the index of prescriptions and drugs, 128.4. The index of physicians' fees (general practitioner, surgeon, and specialist) was 145.2; of general practitioners' fees, 145.2; and of surgeons' and specialists' fees, 144.3. The index of dentists' fees was 160.0 and of hospital rates, 260.7. The price index of group hospitalization, which was recently added to the items priced by the Bureau of Labor Statistics (December, 1950=100), was 103.1 in 1951; thus group hospitalization (Blue Cross premium rates) rose 3.1% during 1951, the first full year covered by this newly added index. Again, with the exception of hospital rates, the indexes of each medical care item were considerably below the Consumers' Price Index. In fact, if the hospital portion of the index of medical prices were excluded, this index would be even lower than the reported level of 155.0.

As the Bureau has previously pointed out, hospitals as buyers of large quantities of food and labor feel the full impact of inflationary forces. They must adjust their rates to cover the vastly increased cost of the materials they purchase. The hospital's costs are not stabilized by such customary accounting items as depreciation and taxes, because most hospitals are charitable institutions. The hospital index may also be uniquely affected by the choice of the base period. While 1935-1939 is considered a relatively normal period by most economists for the purpose of general comparisons, in the case of hospitals it may have some shortcomings. For example, the shortening of the nurses' working day to eight hours, which would considerably affect the labor costs of hospitals, was not fully realized until after 1935-1939. Other changes may have counterbalanced this factor. It is, of course, difficult to judge the appropriateness of a base period for individual items.

Although it is somewhat outside the scope of an article on prices, the decrease in the average length of stay in hospitals should be noted. While hospital rates have increased sharply, the decreased length of stay in hospitals has reduced the average patient's hospital bill considerably. If more information were available, it probably would be possible to make volume or quantity adjustments in the other medical care indexes—adjustments that would carry the discussion into the field of medical care expenditures and away from the topic of prices.

Consumers' Price Index and Price Indexes for Medical Care for Moderate-Income Families in Large Cities for 1949-1951 (1935-1939=100)

	1949	1950	1951
Consumers' Price Index (cost of living)	170.2	171.9	185.6
Medical care and drugs	144.9	147.9	155.0
I. Medical care, excluding drugs	149.7	153.1	160.9
A. Physicians' fees (general practitioner, *surgeon, specialist)*	137.9	140.0	145.2
1. *General practitioners' fees*	137.7	139.8	145.2
(a) Office visit	139.0	140.9	146.0

* December, 1950 = 100.

Source: for Consumers' Price Index, Monthly Labor Review, Bureau of Labor Statistics, U. S. Department of Labor, 74:615 (May) 1952; for medical care price indexes 1949-1951, Indexes *of Retail Prices of Apparel,* Housefurnishings, and Services and Miscellaneous Goods to Moderate-*Income Families in Large Cities,* Quarterly Reports, Bureau of Labor Statistics, U. S. Department of Labor, March, 1950, December, 1951, and March, 1952.

The index of hospital prices is for room rates only. The prices of laboratory and other services are not sampled. The index of prescriptions and drugs does not cover any of the "wonder drugs" of recent years. Realizing the necessity for adding such items and for reflecting certain population changes, the Bureau of Labor Statistics has undertaken a thorough revision of its price index series. The data presented in this article have undergone an interim revision. The complete revision, however, will be presented in the indexes published in 1953. These data will have a new base period, 1947-1949. When the new indexes, which are expected to be more representative of today's cost of living, are issued, the Bureau of Medical Economic Research will present an explanation of the revision and a more complete analysis of medical prices.

Director, Bureau of Medical Economic Research.

BUREAU OF LEGAL MEDICINE AND LEGISLATION

MEDICOLEGAL ABSTRACTS

Blood: Admissibility of Evidence Relating to Blood Type.—The defendant was convicted on a charge of second degree murder and appealed to the supreme court of New Jersey. The defendant was accused of having stabbed the deceased through the heart with a bread knife and then pushing her through a plate glass window, and the issue arose as to whether the fatal wounds were actually caused by the knife or the broken glass. He was arrested and, prior to his trial, was examined by a physician associated with the Board of Health who extracted a specimen of blood for laboratory analysis to determine the presence or absence of venereal disease. The Board of Health, after making these tests, turned over to the police authorities an unused portion of the blood, which was analyzed by them to determine the defendant's blood type. On appeal, the defendant challenged the state's right to use his blood, which it is contended was taken against his will and without his consent, as evidence against him at his trial to show that it was of the same type as that found on the handle of the knife in question. The basis for this challenge was that such an act was a violation of the defendant's privilege against self incrimination, a denial of the process of law, an unreasonable search and seizure, and a violation of the state and federal constitutions.

The defendant alleged that he never gave his blood with the understanding that it was to be used against him at his trial for murder, and, before a consent to such use could be spelled out, the state must show affirmatively that he had full knowledge of all the facts when he permitted his blood to be taken. Although the identical question raised here has never been passed on in this state, said the supreme court, it has been decided in a recent Pennsylvania case. In that case the blood of the accused had been taken without his consent for typing, and he was subsequently convicted of assault and robbery with intent to commit rape. The defendant's blood type was presented at the trial, and objection was made that this violated the defendant's privilege against self incrimination. The Pennsylvania court said that in other jurisdictions it has been uniformly held that the constitutional immunity from self incrimination does not apply to a compulsory examination to determine the prisoner's physical or mental condition for the purpose of testifying in regard thereto, provided, of course, that he be not compelled to answer any questions propounded to him by those making the examination, since the purpose of the immunity is to prohibit the compulsory oral examination of the prisoner, either before or at trial, to prevent his being required to incriminate himself by speech or the equivalent of speech. Taking into consideration the origin and history of the rule of privilege against self incrimination, its scope and purpose and the protection to be afforded thereby, said the supreme court of New Jersey, we have no hesitancy in subscribing to the doctrine enunciated by the above case and other cases that permitted the use in evidence of photographing and fingerprinting and the results of mental examinations. The evidence relating to the defendant's blood type, concluded the court, was not a denial or invasion of the defendant's common law, constitutional, or statutory right or privilege against self incrimination. It was also contended that the taking of the blood against his will for the purpose of using it in evidence was a denial and an invasion of his rights against unreasonable search and seizure. It would seem, said the court, that after arrest is made the person of the accused may properly be examined without a search warrant in order to find evidence of his guilt and that such an examination would not be deemed an unreasonable search. The defendant's further contentions that the state's conduct also violated due process of law and the state and federal constitutions were also overruled, and the use in court of evidence of the defendant's blood type was approved. Accordingly, the judgment of conviction was sustained. *State v. Alexander, 83 A. (2d) 441 (New Jersey, 1951).*

MEDICAL MOTION PICTURES

Seizure: The Medical Treatment and Social Problems of Epilepsy: 16 mm., black and white, sound, showing time 45 minutes. Produced in 1951 by and procurable on loan from Presentation Division, Veterans Administration, Washington, D. C.

This film portrays the problems of a man in whom epilepsy develops following combat experience in the army. In spite of a prepossessing personality, an understanding wife, and other important advantages, his difficulty in holding jobs reduces him to despair and he returns to the Veterans Administration for help. The first 5 or 10 minutes of the film, and many of the later portions, are superb in their sincerity and emotional impact.

There is a scene near the end in which a rather immature physician is trying to comfort the defeated man and the physician seems unable to grasp what really has hurt and worried him. In trying to reassure his patient regarding the inheritability of epilepsy, he fails to emphasize one definite point that should always be made: that epilepsy resulting from physical trauma, chemical poisoning, and organic lesions is not inheritable. This would relieve the worries of a large group of patients, and he could go on to explain to the rest how the need for exact diagnosis justifies the formidable program of history taking, examining, and testing to which the patient is being subjected. At the end, the film bogs down entirely. Surely something has been learned by this time about safe occupations for persons with epilepsy in or out of institutions, and the vocational adjustments that have been found feasible should be suggested by a swift series of brief closing shots.

The photography generally is satisfactory. The animated sequences explaining causes of seizures are well done. The sound on the print reviewed was not consistently of high quality. As the film stands now, with its depressing close, it can be recommended to research workers in the medical and social sciences as a stimulus to better handling of the epileptic patient's problems. If it were provided with a positive, constructive ending it could be shown with telling effect to any mature audience, both lay and professional.

A New Beginning: 16 mm., black and white, sound, showing time 34 minutes. Presented by the United States Army with the cooperation of the Institute of Physical Medicine and Rehabilitation, New York University-Bellevue Medical Center, the United Mine Workers of America Welfare and Retirement Fund, the J.O.B. Committee. Produced in 1951 by Unity Films, Inc., New York. Procurable on purchase from United World Films, Inc., 1445 Park Ave., New York 29.

This documentary film tells the story of Charles Moore, a paraplegic coal miner, whose back was broken in a mine accident. After 10 years of helplessness and inactivity, the United Mine Workers Welfare and Retirement Fund provided means for his rehabilitation. The film shows how Moore, through long and arduous work at the Institute of Physical Medicine and Rehabilitation of the New York University-Bellevue Medical Center, manages to regain a remarkable degree of independence and usefulness. After his training is completed, he obtains a job, "working alongside other men," doing equal work for equal pay.

This is not a training film. Rather, it shows the layman and the physician uninitiated in physical medicine and rehabilitation the processes of rehabilitation in a general way. For that reason it does not cover the details of technique nor the professional aspects of the medical and surgical care of the paraplegic patient. It will be of value in inspiring any disabled person to attempt rehabilitation. The photography and narration are excellent. Except for the fact that it is a bit slow moving at the beginning and at times is overdramatized, the story is well told. The primary audience for this film is the disabled person, but it should also be of interest to any adult who is not familiar with the advantages of physical medicine and rehabilitation.

MEDICAL LITERATURE ABSTRACTS

UNITED STATES

A.M.A. Am. Journal Diseases Child., Chicago

83:421-572 (April) 1952

*Herpes Simplex Virus as Cause of Fulminating Visceral Disease and Hepatitis in Infancy: Report of Eight Cases and Isolation of Virus in One Case. W. W. Zuelzer and C. S. Stulberg.—p. 421.
Corticotropin (ACTH) in Treatment of Acute Laryngotracheitis. J. A. Turner and E. A. Morgan.—p. 440.
*Kerosene Intoxication. R. B. Olstad and R. M. Lord Jr.—p. 446.

Prematurity in the Negro Infant. E. P. Crump, C. Wilson-Webb and M. B. Pointer.—p. 463.

Herpetic Hepatitis in Infancy.—The virus of herpes simplex caused herpes viremia in five newborn infants who did not have pronounced cutaneous lesions. The diagnosis was supported by clinical evidence and postmortem studies, and by isolation and identification of the virus from the liver of one infant whose signs and symptoms were the same as those of the others. The clinical picture of this disease is determined in part by the portal of entry, which may be the conjunctiva, oral mucosa, or skin. Exposure may occur through placental transmission or during passage through an infected birth canal. A systemic reaction to the infection occurs on the fifth to seventh day of life, with temperature elevation or hypothermia, increasing jaundice, lethargy, respiratory distress, vomiting, dyspnea, cyanosis, circulatory collapse, and enlargement of the liver and sometimes the spleen. Characteristic symptoms are accumulation of yellow mucus in the pharynx, a severe bleeding tendency, and hypoprothrombinemia. The essential features of herpes lesions in the internal organs are necrosis and typical intranuclear inclusions. Even if maternal antibodies are present, premature infants are particularly susceptible to this infection, possibly because of a special susceptibility of embryonic tissues. Specific herpetic hepatitis was observed in three older infants (3 weeks, 22, and 18 months old, respectively.) The virus of herpes simplex might have invaded the blood stream of these infants during herpetic stomatitis. It is suggested that viremia is probably a frequent, if not a regular, phenomenon during primary herpetic infections of infancy.

Kerosene Intoxication.—Kerosene intoxication is reported in 71 infants and children. The amount of oil ingested was not always known, but the recorded amounts varied from 5 to 240 cc. Respiratory symptoms were found in all patients, gastrointestinal symptoms in 35, central nervous symptoms in 28, leukocytosis in 39, elevation of temperature in 53, and pneumonia in 29. Proteinuria and/or glycosuria was present in 37 of the 57 patients whose urine was examined. Roentgenograms were taken of 44 patients, 26 of whom had positive evidence of pneumonia in the lower lobes. In 19 patients with positive roentgenographic findings no positive auscultatory findings were recorded. In general, although the period of hospitalization was affected considerably by the presence of pneumonia and fever, it was proportional to the time that had elapsed from ingestion of kerosene to admission. The use of a stomach tube and copious lavage are recommended. The incidence of pneumonia was lower among the children who had vomited and had also received lavage. None of these patients died, but in 325 previously reported cases the mortality rate was 5.85%. Since most of these cases were due to accidental ingestion of kerosene in homes with kerosene stoves, a good preventive measure is instruction of families with this type of stove concerning its potential dangers.

Medical Aspects of Home Cold Waving.—Almost all home cold wave solutions use ammonium or sodium thioglycolate, or mixtures of the two salts, in aqueous solution. Home cold wave solutions are not primary irritants under normal conditions, but irritant dermatitis can occur and is generally traceable to deviations in the method of application. Occasionally the wave solution is left on overnight without rinsing, or the suggested method of neutralization is incomplete. Irritant dermatitis of the hands from home cold wave solution is seen mainly after repeated contact without protection of the hands, as in women who give one or several home waves weekly to friends or relatives. In these subjects an ordinary "housewives' eczema" due to detergents may become exacerbated, or there may be maceration and exfoliation of the skin of the thumb and forefinger bilaterally, due to mechanical trauma incident to rolling up the plastic curlers while the skin is wet with waving solution. The dermatologist may be called on to investigate patchy or diffuse hair breakage, abnormalities in hair texture, or abnormalities in color or odor. Patchy hair breakage may result from excessively tight winding of the tress on the rod. Diffuse hair loss may result in bleached or otherwise damaged hair when failure to follow directions results in overprocessing, and it is occasionally seen following a severe eczematous dermatitis of the scalp. Discoloration of the hair after waving is seen almost entirely in women with dyed hair. Abnormal hair odor is due basically to inadequate application of neutralizer. The odor is particularly noticeable when the hair is rewetted and may be controlled by repeating neutralization. There were no authentic cases of systemic intoxication following percutaneous application of waving agents in the series covered by this report. Mild irritation may be expected after accidental entry of thioglycolate or neutralizer solutions into the eye, particularly if the agent is not flushed out with water.

Pathology of Otosclerosis.—Based on a 25 year experience the author summarizes the present concept of the pathology of otosclerosis by distinguishing between preotosclerotic and otosclerotic changes as follows: The preotosclerotic changes consist of extensive degeneration of the cartilage at the frame of the windows, and overproduction of both precollagenous substance and primitive bone. The broadened marginal sheaths of the blood vessels that may be observed in the preotosclerotic stage, for which the term "blue mantles" has been coined by Manasse, consist of precollagenous substance. These changes are probably hereditary and do not produce clinical symptoms. They are called "preotosclerotic" for the following reasons: they are frequently associated with actual otosclerosis; they occur also without actual otosclerosis; they are not associated with other diseases of the bone of the labyrinth; and they are, as far as the "blue mantles" are concerned, distributed all over the petrous bone. The preotosclerotic changes turn to actual otosclerosis if there are signs of activity, i. e., definite osteoclasis and/or osteogenesis in these areas. By studying the biology of the otosclerotic focus in addition to its histological features, the author concluded that the actual otosclerotic nidus is a genuine tumor of the bone of the labyrinth capsule and shows various microscopic features according to the stage of activity. As in all tumors, the beginning of the disease is scarcely demonstrable. Although otosclerotic tumors have certain features in common with osteoid osteoma, they differ from these tumors in that they are not self-limited and do not grow by expansion, that is, by pushing aside the adjacent structures. The atrophy of the basilar portion of the cochlea, frequently associated with otosclerosis, is probably caused by the same (unknown) factor that causes the formation of the preotosclerotic changes.

Carbon Monoxide Poisoning Due to Domestic Gas Appliances.—Carbon monoxide poisoning has increased in recent years as the result of incomplete combustion of illuminating gas in gas flame refrigerators. The users of gas flame refrigerators are not generally aware that such appliances require periodic adjustment and servicing. They may appear to be operating satisfactorily, without odor, and with a gas flame of the proper color, and at the same time may be discharging dangerous amounts of carbon monoxide. Spot surveys of water-cooled refrigerators in New York City, now fueled with mixed gas and formerly supplied with manufactured gas, have shown that they may be a grave hazard. Of 330 water-cooled refrigerators tested, 156 (59%) were producing dangerous amounts of carbon monoxide. Of 745 air-cooled models, 304 (41%) were operating improperly or were producing dangerous amounts of carbon monoxide. These tests were carried out after the change from manufactured to mixed gas. Carbon monoxide poisoning from gas refrigerators usually occurs more slowly than poisoning due to other gas appliances. With the slow accumulation of carbon monoxide in the blood, the victim usually has headache, dizziness, and muscular weakness. Even before mental confusion develops, the victim may become nauseated and vomit. Mental confusion and helplessness becomes extreme. The victim staggers about; he may overturn furniture and injure himself on broken utensils, frequently leaving a trail of blood stains. In many cases the circumstances give rise to a suspicion of homicide. Health departments and medical examiners' offices should assume leadership in combatting carbon monoxide poisoning resulting from use of gas appliances in the home, and the resources of all official agencies should be utilized.

Treatment of Vascular Headaches.—Two patients, aged 70 and 57, with the uncommon clinical syndrome termed "temporal arteritis" are described. This syndrome is characterized by severe throbbing headache, swelling, and often nodularity of the temporal artery, with erythema of the overlying skin and pain on mastication. There is usually a systemic reaction, with temperature elevation, malaise, muscular aching, anorexia, and weight loss. Blindness due to involvement of the retinal artery may occur in one-third of the cases, as it did in one of the authors' two patients. The pathological picture is one of panarteritis, with necrosis of the media and formation of granulomatous tissue containing foreign body giant cells and epithelioid cells. The intima becomes thickened, and thrombosis is sometimes present. Blindness persisted, but all other manifestations subsided after an illness of two months' duration in the older patient. In the younger patient complete relief of pain and headache promptly followed periarterial infiltration with 1% procaine hydrochloride. It was necessary to repeat this procedure several times, the relief obtained lasting six to eight hours. Nevertheless increasing erythema and brownish discoloration were noted over the right temporal artery, and brief periods of irrational behavior were observed. A 2 cm. segment of the right temporal artery was then excised. Microscopic study of the vessel showed only thickening of the intima. Recovery was considered complete, since the patient remained asymptomatic during a two year follow-up period. Five additional patients are described who were between the ages of 23 and 44 years; they had vascular, usually unilateral, headache of relatively localized origin, with an afebrile course. A small area of hyperesthesia was observed over a segment of the temporal or other extracranial arteries. This headache was dramatically relieved by periarterial procaine hydrochloride infiltration. It is concluded that infiltration with procaine hydrochloride is a valuable therapeutic aid in treating certain headaches, regardless of their etiology. Surgical excision of segments of involved extracranial arteries may be indicated in some cases.

Treatment of Edema with Anion-Cation Exchange Resins.—Of eight patients with moderate to severe edema in whom organic mercurial diuretics were ineffective or contraindicated, seven were treated with a mixture of anion and cation exchange resins of the carboxylic type. This mixture contained approximately 12% anion exchanger, 29% potassium cycle cation ion exchange resin, and 59% hydrogen cycle cation exchange resin. One patient received two types of cation exchange resins; she was first given a resin consisting of 80% ammonium cycle and 20% hydrogen cycle and later the hydrogen-potassium cycle resin. Each resin was administered in equally divided amounts at 10 a. m., 3 p. m., and bedtime to a total of 45 gm. per day. The anion-cation exchange resin mixture was effective in restoring responsiveness to organic mercurial diuretics in three of five patients. The two unresponsive patients may have had edema unassociated with sodium retention. Typical symptoms and electrocardiographic changes suggestive of potassium depletion developed in the patient in whom the two types of cation exchangers were used. Acidosis and over-depletion of sodium and potassium are the commonest hazards associated with the use of any cation exchange resin. In one patient with intercapillary glomerulosclerosis, the cation resin administered alone caused such a rapid decrease in the carbon dioxide combining power that its further use was considered inadvisable. The anion-cation mixture resulted in less acidosis and better control of edema. The presence of renal disease need not be considered an absolute contraindication to resin therapy. Periodic laboratory determinations of serum sodium, potassium and chloride levels, and carbon dioxide content or combining power, are desirable in all patients and essential in those with preexisting renal disease. It would seem that the use of cation exchange resins, as adjuvants to an anion exchanger, will assume a prominent place in the management of selected cases of edema, since sodium depletion can be achieved and the action of organic mercurial diuretics potentiated or restored by the use of these resins.

Effect of Cortisone and Corticotropin on Lesions of Rheumatoid Arthritis.—Muscle biopsies were performed on 30 patients with rheumatoid arthritis prior to and during hormone therapy. Both inflammatory and degenerative lesions were found in the muscles of 18 of the 30 patients, but in only 11 did the changes seem suitable for the evaluation of hormonal therapy. In 8 of the 11 patients there was definite improvement in both types of lesions following administration of cortisone (cortone®) and corticotropin (ACTH). The inflammatory nodules disappeared in five and were improved in the other three patients. Degenerative muscle changes improved less than the inflammatory lesions in eight patients. The greater response of the inflammatory lesions seems understandable in view of the short periods of treatment. Subcutaneous rheumatoid nodules were altered considerably in the 12 patients in whom they were studied during the period of hormone administration. Many small nodules almost disappeared, while the large nodules became smaller, less painful, and less inflamed. There was a definite histological change in two of the three patients from whom comparable nodules were removed before and during therapy. Synovial inflammation decreased in both patients in whom articular biopsies were performed before and during hormone therapy. No delay occurred in the clinical healing of the surgical wounds of this group of patients during cortisone or corticotropin administration.

Diffuse Interstitial Pulmonary Fibrosis.—In 1944 four cases were reported of a disease characterized by relatively sudden onset of dyspnea, cough, cyanosis, elevation of temperature, and early signs of cardiac decompensation. Death resulted within a short time from acute asphyxia or heart failure. At postmortem examination the lungs contained diffuse interstitial fibrotic changes. One similar case had been described in 1940 and subsequently reported cases, including the one reported here, bring the total to 14. The patients included six men and eight women ranging in age from 21 to 68 years. The main symptoms were cough, expectoration, hemoptysis, chest pain, fever, dyspnea, and cyanosis. In a few cases the onset was insidious, but in most it was acute. With the appearance of dyspnea and signs of heart failure, the disease progressed rapidly, with death resulting from suffocation or cardiac decompensation. The duration varied from one month to three and a half years. Clubbing of fingers and toes was noted in several cases. Miliary, nodular, or mottled infiltrations, involving diffusely both lungs, were seen frequently, and often were associated with conglomerate areas of consolidation and occasionally pleural effusion. The differential diagnoses included tuberculosis, atypical pneumonia, chronic pulmonary infection, pulmonary edema with pneumonia or cardiac disease, pulmonary manifestations of systemic disease, such as blood dyscrasia, amyloidosis, and allergic conditions, as well as metastatic neoplasm. In the case described here roentgenographic findings suggested sarcoidosis. At autopsy diffuse interstitial fibrosis of both lungs was found. The progressive nature of the disease was indicated by the presence of different stages of the fibrotic reaction in various parts of the lungs. Associated cardiac enlargement affected chiefly the right heart. It is suggested that the disease is caused by a virus. Recovery may take place in some cases, but this cannot be proved, since the diagnosis depends on a complete autopsy.

Three Cases of Nocardiosis.—Nocardiosis is an acute or chronic infectious disease of granulomatous or suppurative nature, caused by an aerobic, gram-positive, inconstantly acid-fast species of Actinomycetaceae. Nocardia asteroides is the organism most frequently isolated. The authors add 3 cases to the 43 recorded in the literature. In case 1 the diagnosis was established before death, but treatment was ineffectual. Whether the preexisting silicosis predisposed to nocardiosis can only be conjectured. Case 2 illustrates the frequent association of pulmonary and neurological manifestations; in contrast to case 1, antemortem studies failed to reveal the etiological agent. The third patient was cured, and there has been no evidence of recurrence during a four year follow-up. The similarity of the signs and symptoms to those of pulmonary tuberculosis was striking. Since nocardiosis may mimic pulmonary tuberculosis, it is important to know that fragmented acid-fast mycelia in sputum may be mistaken for Mycobacterium tuberculosis. In the cases reported to date, the organisms have been more sensitive to sulfadiazine than to antibiotics. Surgical drainage should be employed when indicated.

Baseball or Mallet Finger.—Avulsion of the distal attachment of an extensor tendon may result from a blow to the tip of the finger, forcing the finger into sudden flexion, or of a blow to the dorsum of the finger, injuring the extensor aponeurosis of the distal phalanx. A chip of bone may be detached with the end of the tendon. The trauma may be caused by a ball striking the end of the finger (hence the term "baseball finger"), and another name for the condition is "mallet finger." Two closed methods of treatment have been described. One is to place a long splint, such as a Lewin splint, on the finger with both interphalangeal joints extended. Usually, however, since the flexor tendons are so much stronger than the extensor tendons, the splint fails to keep the extensor relaxed enough to effect a union of the torn aponeurosis. The other, described by Smillie and by Watson-Jones, employs a plaster cast. This is applied to the finger with the proximal interphalangeal joint flexed and the distal interphalangeal joint extended. It has great merit theoretically, but unfortunately, the cast has the disadvantage of sliding on the finger. The method with which these authors obtained good results in all of nine cases in which it was used utilizes a very short splint, which must not extend proximally farther than the interphalangeal joint. This joint will remain flexed, since a finger that is not used is constantly in the position of relaxation, in this case, flexion. Thus the goal of Smillie and of Watson-Jones is achieved in that the proximal interphalangeal joint is in flexion while the distal interphalangeal joint is in extension. Since the splint is short, it can be worn with little discomfort for the eight weeks necessary to insure union of the aponeurosis. The patient's comfort is increased by removal of the splint at two week intervals. The only one of the nine patients who did not obtain full extension did not start to wear the splint until three weeks after injury, yet even he obtained a satisfactory result.

Folic Acid in Leukemia.—Reports on the use of metabolic antagonists of folic acid in leukemia revealed that in some patients a partial, temporary remission follows the administration of a folic acid antagonist. These remissions occur for the most part in patients with acute leukemia, particularly those in the younger age group, whereas the results of treatment in chronic leukemia are in general unsatisfactory. Moreover, in patients with chronic leukemia, the administration of an antagonist is usually accompanied by early severe toxic manifestations such as erythema, stomatitis, hemorrhage, and anorexia. Therefore, it appears that a general systemic factor that determines the individual response to folic acid antagonists must vary in different types of leukemia. It seemed possible that the metabolic availability of folic acid itself might be such a factor, and an attempt was made to determine the nutritional status with respect to folic acid in cases of chronic and acute leukemia. Folic acid excretion following test doses of the vitamin was measured in 31 cases of leukemia. Evidence was obtained that depletion of body stores of folic acid occurs in many cases of leukemia. It is suggested that the patient with leukemia has an increased requirement for the vitamin due to his hypermetabolic state, or perhaps more precisely, to the production of large numbers of immature leukocytes with relatively high folic acid concentrations. Since patients with chronic leukemia more commonly show evidence of greater folic acid depletion than those with acute leukemia, it appears that duration of the disease may be a factor in exhausting tissue reserves of the vitamin. The degree of folic acid nutritional depletion seems related to the varying clinical results obtained with antagonist therapy in chronic and acute leukemia.

Resuscitation Methods.—Gordon and associates studied resuscitation methods on five men made apneic by means of intravenous thiopental (pentothal®) sodium and *d*-tubocurarine chloride. In pole top resuscitation, the rescuer ascends to the victim. He secures his safety strap around the pole and places the victim astride it between himself and the pole. He encircles with his arms the waist of the victim, placing both hands on the abdomen, thumbs below the lower ribs and fingers touching. With his arms and hands, he compresses the victim's abdomen in an upward motion. At the finish of the stroke, the hands are cupped with the fingers depressing the abdomen under the rib margin. The pressure is quickly released and reapplied 12 to 15 times per minute. The pole top method of resuscitation gives adequate ventilation, and should be applied to linemen who are shocked on the poles. However, since the vertical position predisposes to peripheral stasis and circulatory embarrassment, and impedes drainage of fluids that may collect in the oropharynx, the victim should be lowered to the ground and one of the more efficient push-pull methods begun as soon as he can be placed in the prone position. Comparative tests of the manual resuscitation techniques revealed that push-pull methods are two to three times as efficient, as regards pulmonary ventilation, as either the push or the pull methods alone. For general purposes the arm lift, back pressure method (modification of the Danish Nielsen method) should be used, since it is easy to teach, can be performed by most operators for prolonged periods, and gives excellent pulmonary ventilation without circulatory embarrassment. Trained personnel should also be acquainted with the hip lift, back pressure and Silvester arm lift, chest pressure methods to be used as alternatives in special circumstances.

**Prolonged Intercostal Nerve Block in Upper Abdominal Surgery.* W. J. Puderbach and H. E. Shaftel.—p. 200.

Prolonged Intercostal Nerve Block in Upper Abdominal Surgery.—Pulmonary complications of upper abdominal surgery have been attributed to decreased respiratory excursion due to postoperative pain. Intercostal nerve block with 1 to 2 cc. of a stable solution of procaine and butyl aminobenzoate in a water miscible nonoily vehicle ("efocaine") was given a therapeutic trial for control of postoperative pain in 30 patients between the ages of 36 and 64. Of these 30 patients, 18 submitted to cholecystectomy, 1 to cholecystotomy, 1 to gastrectomy, 2 to mastectomy, 5 to operations for epigastric hernia, and 3 to operations for ventral hernia. Postoperative pain control was achieved to a high degree, permitting freedom of movement, deeper breathing, and coughing. Twelve patients had no local postoperative pain and required no narcotic or sedative medication. Fourteen had mild pain or were uncomfortable for the first 24 to 30 hours and required one to two doses of sedative medication. Three received three doses of sedative medication and one required five doses. The patients who had had intercostal nerve block received an average of 0.7 doses of postoperative medication as compared to 5.2 doses required by a control group of patients undergoing similar surgical intervention by the same surgeons. Local anesthesia lasted for from 8 to 21 days, the mean duration being 14.2. There were no local or systemic toxic manifestations. There was no interference with healing of the incision.

Selenium and Dental Caries.—Since "bad teeth" was reported to be one of the most pronounced symptoms in populations living in a seleniferous area, the authors of this paper decided to collect further data on the relationship between selenium and dental caries. Urinary selenium concentrations were determined in native-born school children reared in the counties of Clatsop and Klamath of Oregon where high and low rates, respectively, of dental caries were known to exist. Previous studies indicated that fluoride content of the drinking water, availability of dental services, and quantity of candy bars and carbonated beverages consumed were not the factors for the observed wide differences in caries incidence. A direct relationship was found between the prevalence of dental caries and the urinary selenium concentrations, suggesting that, in an as yet unknown manner, the trace element selenium may render the teeth more susceptible to caries.

Duodenal Ulcer With and Without Vagotomy.—During the past five years over 400 patients have been treated at the Cleveland Clinic by vagotomy and gastroenterostomy. Seven of the first 154 patients could not be traced, but the remaining 147 have been followed for from two to four years. Good results have been obtained in 90% of the patients followed. Another 3% have had no recurrence of ulcer symptoms, are better than before operation, but have side-effects of the operation or gastrointestinal symptoms arising from causes other than an ulcer severe enough to require some form of dietary or medical treatment. In 10 patients (7%) the results are classified as failures. The 90% of patients in whom satisfactory results were obtained are following no diet, taking no medicine, and are permitted to eat, drink, and smoke as they please. They have been informed that they no longer have the ulcer diathesis and that they can forget that they ever had an ulcer. The majority of these patients make the unsolicited comment that they have never felt better in their lives. A recurrence after vagotomy and gastroenterostomy can be dealt with by resection, with a mortality rate no higher than that of a primary resection, but there is no known cure for the gastric cripple who does poorly after a radical gastrectomy. Because the mortality rate of vagotomy and gastroenterostomy is less than 0.5% in over 400 cases, because the morbidity and incidence of side-effects are lower than with gastric resection, and because in 95% of the cases there is no evidence of recurrent ulceration for from two to four years after operation, Crile believes that vagotomy combined with gastroenterostomy is the best operation for patients with complicated duodenal ulcer.

Lead Poisoning in Young Children.—Chewing of paint from cribs, toys, furniture, and window sills, and eating of painted plaster and fallen paint flakes causes lead poisoning in childhood. Putting things in the mouth, though normal in the first year of life, is abnormal if continued much later and is referred to as pica, or perverted appetite. Children of teething age living in old, run-down houses where lead paint has been used for years are especially likely to have lead poisoning. Weeks or months following repeated ingestion of small amounts of lead, there may appear irritability, fretfulness or disturbed gastrointestinal function, such as lack of appetite, constipation, vomiting or cramps; there may also be pallor as the result of secondary anemia. More severe intoxication results in lead encephalitis, which may terminate in death. Central nervous system involvement or encephalopathy, rarely seen in adults with lead poisoning, is common in children, whereas peripheral neuritis, a lead line on the gums, and colic are usually absent in children. A history of pica and examination of blood smears for stippling of the red blood cells are important aids in diagnosis. Porphyrinuria is frequently found, and the demonstration by roentgenogram of an increased density in the growing ends of the long bones is a cardinal sign of lead poisoning. The quantitative determination of lead in blood or urine is helpful in diagnosis. Williams and associates review the efforts made in the Baltimore City Health Department to diagnose and treat plumbism in infants. Education of the public combined with "lead consciousness" in physicians and pediatric clinics and with a blood-lead laboratory service has resulted in a marked increase in case recognition. It is hoped that education and the enforcement of measures regulating the use of lead-containing paints will result in a material reduction and eventual elimination of lead poisoning in children.

Cortisone in Frostbite.—Inasmuch as no satisfactory treatment for frostbite in the stage after rewarming was available, the metabolic research facility studied the effect of cortisone. Patients were placed on a standard diet with a fixed calculated intake of calories, nitrogen, sodium, potassium, and phosphorus. Balance studies were conducted on these elements. Antibiotics were used when indicated, and physical activity about the ward was encouraged. The treated patients and controls were "paired" as to severity of injury as far as possible. The treated group of eight patients received 100 mg. of cortisone in one intramuscular dose daily. Because no satisfactory placebo was found, none was used in the untreated group. *Cortisone exerted no significant clinical effect on the progress of the frostbite injuries; no significant metabolic effects were noted in the treated group.*

*Case of Arteritis Temporalis Treated with ACTH. H. P. Østergård Kristensen.—p. 391.

Corticotropin in Treatment of Temporal Arteritis.—Temporal arteritis is characterized by chronic arteritis and periarteritis. Histologically it is manifested by formation of granulation tissue in the intima and media, with exudation in the adventitia and round-cell infiltration around the vasa vasorum. Postmortem microscopy of the arteries has now established that the lesion is a general chronic arteritis, as characteristic changes have been found in almost all the arteries of the body. Thus the lesion in the temporal arteries is to be regarded as the symptom that most frequently leads to the diagnosis. A woman, aged 71, with the typical symptoms of this disorder is described. For months she had had pains in the occipital region and lately also in both temporal regions. Her temperature was elevated. The temporal arteries were almost as thick as a pencil and of bluish color; they felt sclerotic. A segment of the frontal branch of the left temporal artery was removed, and it showed pathological changes. After several therapeutic measures, including administration of antihistamines and antibiotics, had proved largely ineffective, treatment with corticotropin was started and continued for about a month. The effect was prompt; the pain subsided, the temperature and sedimentation rate decreased, and the patient's general condition improved. When this therapy was discontinued, the temperature again increased and the sedimentation rate rose to the same level as prior to the institution of treatment, but the patient had no recurrence of pain. The author suggests that corticotropin treatment, possibly intermittent, combined with bishydroxycoumarin therapy, might improve the prognosis of temporal arteritis by preventing progression of the arteritis in some vital regions.

Altered Consciousness in Brain Stem Lesions.—Jefferson points out that alterations of consciousness may arise from lesions of the brain stem and describes in detail six patients who had disturbances of consciousness associated with signs of mesencephalic disorder. The first patient had a history of nine attacks of pathological sleep, each lasting up to a week. Initially they occurred without focal signs, but later were associated with indications of disorder of function in the mesencephalic and upper pontine tegmentum. The causal lesion seemed to be an angioma. In the second patient disturbances had started two and a half years before, with variable bilateral ptosis. After a year there was a sudden episode in which consciousness was lost for an hour; simultaneously further ocular signs and rigidity of trunk and limbs developed, all indicating a disorder at the mesencephalic level. After this she remained torpid for a week. In subsequent months she had three similar attacks. The third patient had symptoms of mesencephalic derangement, including fixed pupils, ptosis, external ocular palsies, nystagmus, bilateral pyramidal and cerebellar signs, some disturbance of postural and vibration sense, and dysarthria, together with evidence of spontaneous subarachnoid bleeding. He was somnolent for three days, and lethargic a fortnight longer. There was incomplete recession of neurological signs. A congenital anomaly of blood vessels in the region of the upper brain stem was suspected. The symptoms in the fourth patient also indicated a midbrain tegmental lesion, which, judging from the family history, seems to be caused by angiomatous malformations. The fifth patient had two attacks (at an interval of 10 years) of midbrain disorder, the first known to have been associated with subarachnoid bleeding and the second presumptively so. In the second attack there was loss of consciousness for 36 hours followed by pathological drowsiness and resultant amnesia of five weeks' duration. A brain stem vascular anomaly seems likely. The sixth patient had a pulmonary infarct and a few days later had brain stem embolism. She was stuporous for 18 hours, and in a state of somnolence for a week, with clinical signs of a mesencephalic lesion. Physiological studies suggest that when parasomnic symptoms occur clinically with brain stem disorders, they indicate encroachment of disease on the reticular substance. This has to be proved or disproved by pathological study.

Neurological Manifestations of Hypoparathyroidism.—That deficiency of parathyroid hormone secretion results in hyperexcitability of the peripheral nervous system (tetany or spasmophilia) is well known, but the other neurological manifestations of the tetany syndrome are less familiar. This paper presents the histories of two patients with idiopathic hypoparathyroidism. The syndrome consisted of tetany, trophic ectodermal lesions, skeletal abnormalities, and biochemical changes in the blood. Both patients had hemitetany for several months before this sign became bilateral. There was no evidence of gross cerebral disease. In case 1 the child also had epilepsy, acute hallucinatory psychosis, mental deficiency, a transient choreiform state, separation of cranial sutures, and calcification of the choroid plexus at an unusually early age. The electroencephalogram in case 1 showed a diffuse slow rhythm that increased to alpha frequency (with occasional delta activity) when the serum calcium was restored to normal. In case 2 the electroencephalogram of an adult showed mild dysrhythmia that was probably within normal limits. Attention is drawn to headache, excessive muscle weakness, and fatigue as symptoms of incipient tetany. Tests for latent tetany are reviewed and their mechanisms discussed.

Retrolental Fibroplasia.—A team from the Oxford Eye Hospital, the pediatric department of the United Oxford Hospitals, and the Nuffield Laboratory of Ophthalmology has been concerned in a joint investigation of retrolental fibroplasia since June, 1950. All prematurely born babies of low birth weight were subjected to routine ophthalmologic examinations. The infantile optic disk is always extraordinarily pale, and the central fundus often has a patchy distribution of pigment. The retinal periphery constantly has a peculiar edematous-looking greyness, gradually merging into the pinkness of the posterior fundus. These appearances have been seen in both full-term and premature babies, and they gradually disappear during the first weeks of life. The periphery of the infant lens is often doubly refractile, and this may lead one to suspect a detachment of the retina when in fact there is none. The authors are sure that diagnosis of retrolental fibroplasia cannot be made without the presence of a retinal detachment or thickening, or of some retrolental mass near the periphery. In addition to these signs engorgement of the retinal vessels and formation of "fans" of new vessels from the retinal vessels, often coming forward into the vitreous in front of the thickened or detached retina, are important diagnostic points. They do not regard retinal vascular dilatation alone as sufficient to warrant a diagnosis of retrolental fibroplasia. A total of 22 cases of retrolental fibroplasia have been observed at the Oxford hospitals since 1947. The authors gave corticotropin by intramuscular injection in four doses daily, totaling 20 to 25 mg., to six infants with retrolental fibroplasia and felt that the disease was arrested by this treatment. Despite gross intraocular damage, many of the eyes retain sufficient vision to enable the child to avoid obstacles and to walk about unaided. Excision of the eye is unnecessary, and is to be avoided in view of this possibility.

Tuberculosis in Families with BCG-Vaccinated and Non-Vaccinated Children.—Many workers have reported surveys demonstrating the protective value of BCG vaccine, but others found little evidence to support this view. The problem of carrying out controlled investigations to cover all possible variables has made it difficult to assess its true value. A search was made for families in which some children had been vaccinated with BCG and others had not, and which had been exposed to a known source of tuberculous infection. This paper presents data on 16 families with 22 vaccinated and 22 nonvaccinated children. The source of infection, while not the same for all children, was at least similar. When the source of infection was in the home, it may be assumed that each child was exposed to the maximum possible risk. The social conditions, especially overcrowding, varied between families, but the children in each family lived under the same conditions and their standard of nutrition tended to be the same. The reason that some of the children were vaccinated and others were not was probably that the mother was offered vaccination for some of the children on one particular occasion, for example, at a school medical examination, a child welfare center, or a maternity hospital, but did not trouble to have the remaining children vaccinated. Primary tuberculosis developed in 21 of the 22 children in the nonvaccinated group. In the BCG-vaccinated group, two at most showed some evidence of superinfection. The protective value of BCG vaccination is striking, both when the source of infection is within the family (with the maximum risk for each child) and when it is outside. The difference in the incidence of tuberculosis in the vaccinated and nonvaccinated children admitted to a hospital is recorded. The absence of tuberculous meningitis and miliary tuberculosis in the vaccinated group is noted.

Methionine Test for Liver Function.—Amino acids, particularly methionine, are increased in the serum of patients with liver damage. This suggests that it is difficult for the damaged liver cell to metabolize or store methionine. In preliminary tests the authors determined that after a tolerance test with methionine the serum of patients with liver disease showed higher methionine values than the serum of healthy persons. Since, however, determination of methionine in the serum requires complicated microbiologic or colorimetric tests, it was regarded as unsuitable for a routine liver function test. It was decided to determine the methionine level in the urine, especially since a simple as well as specific colorimetric method is available for this purpose, namely, the McCarthy-Sullivan reaction. The authors used this test in a modified form, which corresponded largely to a modification described by Horn, Johnes, and Blum. In this liver function test methionine is given by mouth, and its excretion in the urine is ascertained over the next 24 hours. Healthy adults excrete in their urine from 11.5 to 13% of orally administered methionine. The authors regard the elimination of from 15 to 19% as abnormally high and over 19% as definitely pathological. In children, excretion of over 15% is to be regarded as definitely pathological. The authors hope that, in view of the simplicity and cheapness of the test, it will find wide application.

Cytological Studies in Early Diagnosis of Malignant Tumors.—Since Mohr's report in 1949, he and Többen have been able to study an additional 317 cases in which carcinoma was suspected on clinical grounds by means of Papanicolaou's cytological technique. Gynecologic and bronchial carcinomas accounted for most of the cases. They found that under unfavorable conditions correct results will be obtained in 37% of the cases and under favorable conditions in 93%. Doubtful results are to be expected in from 3 to 28% of the cases and false diagnoses in from 2 to 25%. Caution is therefore necessary, since a negative or doubtful result never excludes the possibility of a carcinoma. Only because of its simplicity can the cytological method be regarded as an advance in the early diagnosis of carcinoma. Its use can be recommended in material that can be obtained by a direct smear. Indirectly obtained material, such as puncture fluids, gastric juice, or bronchial, or prostatic secretions, do not provide reliable results. Although the method provides helpful indications, it must be verified by biopsy. It must be used cautiously as a basis for therapeutic measures and for prognostic evaluation.

Total Colectomy.—Kerr demonstrates on the basis of three case histories that total colectomy has a place in the treatment of both ulcerative colitis and familial polyposis; that with the aid of modern anesthesia, antibiotics, and blood transfusions the risks are not high; and that in the presence of a permanent ileostomy, life can be both useful and happy. The surgical program is a formidable one, and is usually carried out in three stages at intervals of about three months. The first stage consists of division of the ileum and formation of a permanent ileostomy. Removal of the distal ileum, cecum, ascending colon, transverse colon, and descending colon represents the second phase, and removal of the sigmoid colon, rectum, and anal canal the third phase. Discussing the management of ileostomy Kerr says that within a few days of the establishment of an ileostomy its products become less fluid, but they do not acquire the solidity seen with a sigmoid colostomy and cannot be satisfactorily managed with a simple dressing and belt. The problem for most patients is solved by the Koenig-Rutzen bag, a soft rubber bag attached to a rubber collar, which in turn is secured to the skin with a special adhesive solution. None of the patients had continuing distress in handling the ileostomy. Familial polyposis of the colon is the less controversial of the two conditions for which Kerr employed total colectomy. In this patient carcinoma developed low in the rectum so that there could be no conservation of the rectum or anal canal. The minimal operation therefore was excision of the rectum and sigmoid colon. Some would have advocated watching the remaining colon, but this would not have been safe, since the patient had extensive papillomas and continued to bleed from her colostomy. The two patients with ulcerative colitis raise the question under what circumstances ileostomy for ulcerative colitis should be followed by total colectomy. The indications in these two patients were the continued diarrhea and blood loss. The threat of carcinoma must also be considered, because the surviving epithelium at the margins of ulceration is shaggy, edematous, and often hyperplastic, changes which some regard as precancerous.

Atheroma of Renal Arteries in Kimmelstiel-Wilson's Syndrome.—The fact that more severe atheroma at a much earlier age develops in many diabetics than in the general population has been known for many years, but no particular significance appears to have been attached to excessive atheroma of the renal arteries in diabetics. It is the purpose of this paper to show that such atheroma may produce extensive structural changes in the kidney, which are of considerable significance in relation to Kimmelstiel-Wilson's syndrome. Two types of glomerular lesions occurring in diabetic glomerulosclerosis, the nodular lesion and the exudative lesion, are briefly described on the basis of the findings in a series of 135 diabetics. The clinical and postmortem findings in eight cases of Kimmelstiel-Wilson's syndrome in which death resulted from uremia are recorded. Gross atheroma with much narrowing of the renal arteries was present in all eight cases. Atheromatous involvement of the large and small branches of the renal artery gives the kidney a characteristic macroscopic appearance. The histological picture in all eight cases was distinctive, the predominant feature being ischemic obliteration of vast numbers of glomeruli. Atheroma of the renal arteries of comparable degree was seen in only one other case in which similar clinical and histological features were not present. In 43 other cases of diabetic glomerulosclerosis there was no evidence that the renal lesion, uncomplicated by renal artery atheroma, was responsible for death. The pathogenesis of the massive obliteration of glomeruli is discussed, and it is concluded that obliteration results from atheromatous narrowing of the renal arteries superimposed on severe arteriolosclerosis.

Resection in Primary Tuberculosis.—Dijkstra discusses the indications for pulmonary resection in primary tuberculosis on the basis of five cases in which the continued discharge of tubercle bacilli indicated resection of the lung. Surgical treatment is rarely necessary in the beginning phase of the primary infection, because in most cases the pathological process seems to become arrested, although repeated sputum examination and gastric lavage may reveal the intermittent discharge of bacilli. In other cases there seems to be a long period of clinical arrest (from two to five years), after which the sputum cultures again become positive. Caseation of the lymph nodes with rupture into the bronchi, frequently associated with specific changes in the walls of the bronchi, was the commonest cause of the continued discharge of tubercle bacilli. In such cases conservative treatment is not adequate and resection is advisable. The sputum should be cultured frequently and over long periods in patients with primary pulmonary tuberculosis.

*Disodium Salt of Congo Red and Streptomycin in Tuberculous Infections. G. Pescetti and E. Destefanis.—p. 189.
Thiosemicarbazone in Extrapulmonary Tuberculosis. G. Oppia.—p. 196.

Streptomycin Combined with Congo Red in Tuberculous Infections.—The failure of streptomycin to cure tuberculous infections has been attributed to the inability of the drug to penetrate and diffuse into the specific foci. To test this hypothesis, the authors combined streptomycin with congo red and obtained a double disodium salt that in vitro maintained, and sometimes enhanced, the antibiotic properties of streptomycin. In addition, because of phagocytosis of congo red, the antibiotic could penetrate and concentrate into the foci. Four groups of guinea pigs, of which one served as a control, were inoculated intraperitoneally with Mycobacterium tuberculosis. One month later one group was treated with intracardiac injection of congo red every other day, one group with intramuscular injection of 0.01 gm. of streptomycin in 1 cc. of isotonic sodium chloride solution every day, and the third with intramuscular injection of 0.01 gm. of streptomycin combined with 1 cc. of congo red every day. The experiment lasted 257 days, and the observation period after the treatment 135 days. All the control guinea pigs, all those that received congo red, and 25% of those treated with streptomycin died. There was no death among those treated with the salt. During the treatment reaction to tuberculin was positive in 90% of the animals treated with congo red, negative in 40% of those treated with streptomycin, and negative in all those treated with the salt. In some of these it became positive when treatment was interrupted. All the guinea pigs lost weight after the inoculation, regained it during treatment, and lost it again after the treatment was discontinued. Only those that were treated with the salt began to regain weight after a few days and exceeded their initial weight. The authors also made histological studies of these animals, and concluded that streptomycin combined with congo red arrests the infection and attenuates the toxic phenomena in tuberculous guinea pigs more than streptomycin alone. Moreover, if the infection reactivates after treatment is interrupted, it is a mild process with productive, fibrotic, and cicatricial tendencies. The authors, encouraged by these results, are now using the salt to treat patients with tuberculosis. The effects seem encouraging, but a definitive evaluation is still premature.

Study of Blood Volume in 60 Patients With Pulmonary Tuberculosis; Its Significance in Surgical Treatment. Cornet and Duhamel.—p. 322.

Ligation of Inferior Vena Cava in Cardiac Decompensation.—Ligation of the inferior vena cava was performed on 15 patients between the ages of 13 and 61 years with cardiac decompensation. There was no operative death. Immediate improvement of the respiratory embarrassment was obtained by all the patients, but despite immediate satisfactory results, one patient died from cardiac decompensation and uremia three weeks after the operation. Three patients died within the first three postoperative months; two of these patients had mitral lesions associated with asystole, and the third had asystole complicating persistent ductus arteriosus. Three additional patients died three, five, and nine months respectively after the operation; two of these had mitral lesions associated with asystole, and one had cor pulmonale and angina pectoris. Of the eight surviving patients, two were still incapacitated four and six months after the operation. Satisfactory late results were obtained in the remaining six patients; two of them had no functional disturbance and resumed their normal activities five and three months after the intervention. The others were considerably improved, but the functional signs of their heart disease had not subsided completely. These results corroborated those reported by other workers, and showed that ligation of the inferior vena cava induces immediate improvement that may be followed by death within the first six operative months, while permanent improvement may be obtained by 50% of the patients operated on. Use of local anesthesia and a retroperitoneal rather than transperitoneal approach was considered responsible for the satisfactory results. Poor general condition is the only contraindication to the operation in young patients. Lesions of the aortic valve are not considered contraindications. Indications are most favorable in patients whose stasis is limited to the lungs; they are less favorable in those with stasis of the lungs and the liver, and least favorable in those with visceral stasis associated with edema. Ligation of the inferior vena cava should be considered even in a cardiac patient with mitral lesions and considerable dyspnea on effort in the absence of rales at the base of the lungs and of enlargement of the liver, after treatment with mercurial diuretics, salt-free diet, and thevetin has failed.

Aureomycin and Terramycin Treatment of Human Enteroprotozooses. J. Faiguenbaum, M. Miranda, A. Neghme and M. Agosin.—p. 99.

Regression of Pulmonary Metastases with Androgens and Estrogens.—The authors have treated more than 80 patients with breast cancer since 1944 with implants of androgens (methyltestosterone, testosterone propionate, and testosterone); 9 of the patients also had estrogen implants (diethylstilbestrol or hexestrol). A review of 64 of these cases showed that the patients had had 304 hormonal implants (252 of methyltestosterone), amounting usually to 300 mg. every three to four months (average duration of treatment, 24 months with a total dose of 1.07 gm. of hormone). Pulmonary metastases usually occur in the final stage of the disease and end in death within a short time. Fifteen patients, all past the menopause, in this series had pulmonary metastases; in 11, the response to hormone therapy was favorable. This exceeds the figures given by the Council on Pharmacy and Chemistry of the American Medical Association, which reports improvement in only 13% of such cases. Treatment was given for an average of 27 months to these patients, about 300 mg. of androgens being given every three to four months. Larger doses do not seem to give better results; length of treatment is more important than size of dose. Striking regression of pulmonary metastases was obtained in two cases with small doses of synthetic estrogen, 100 mg. per implant, a fact requiring further study. Average survival from start of treatment was 19.3 months, which is longer than generally reported (radiotherapy, 12 months; hormone therapy, 8.9 months). Most of the patients were treated with methyltestosterone, which may be more effective than other androgens in antitumoral properties, especially when administered parenterally. The change of hormones, or the influence of an estrogen following an androgen, may also have affected the favorable outcome; in many cases, improvement was observed after the antitumoral effectiveness of the androgen had been exhausted.

BOOK REVIEWS

Calculation of Industrial Disabilities of the Extremities. By Carl O. Rice, M.D., M.S., Ph.D., Clinical Associate Professor of Surgery, University of Minnesota Medical School, Minneapolis. Cloth. $10.50. Pp. 289, with 160 illustrations by Jean E. Hirsch. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 49 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, 1952.

In this monograph the author has developed a detailed objective approach to the evaluation of industrial disabilities limited to the extremities. In the preface, it is stated that the information is intended to be of specific assistance to the physician in determining disability, a guide to the industrial commissioner in setting weekly indemnity values, and an aid to the insurance adjuster in estimating insurance reserves. The well-delineated table of contents and index provide easy reference to the subject matter.

In the opening chapter, there is a brief review of the methods used by Kessler, McBride, and others. To the author, it seems that methods for calculating disability that give unit values for pain, incoordination, adaptability, and similar intangibles are of little more value than a good guess and are accurate only in proportion to the experience of the physician who makes them. Dr. Rice states that it is his assumption that, when the useful range of motion is used as a basis for calculating disability, almost all other factors have already been given consideration.

The section dealing with relative values explains the protractor system used by the author in arriving at values for all of the joints of the extremities. He feels that it is the responsibility of the physician to determine the percentage loss of function in the involved member and that the industrial commission should render the award. A plea is made for standardization in the compensation laws, so that anatomic and functional values will be the same in all states.

The author implies that he recognizes the limitations inherent in any system of disability evaluation by stating that he is endeavoring to establish some degree of standardization in a field that almost completely defies it. This book should prove especially useful to those physicians who are called on to make only an occasional estimation of disability.

Dynamic Psychiatry. Edited by Franz Alexander, M.D., and Helen Ross. Cloth. $10. Pp. 578. University of Chicago Press, 58th St., and Ellis Ave., Chicago 37; Cambridge University Press, Bentley House, 200 Euston Rd., London, N.W.1, 1952.

This comprehensive volume consists of 16 articles written by 15 distinguished specialists and practitioners. Part 1 is concerned with theoretical concepts of dynamic psychiatry, such as development of fundamental concepts of psychoanalysis, dreams and rational behavior, history of metapsychological concepts, and personality development. Part 2 is concerned with clinical problems in psychiatry. In this section are articles on neuroses, behavior disorders and perversions, acute neurotic reactions (based on the study of war neuroses), emotional disorders of childhood, psychodynamic approach to the study of the psychoses, and principles of psychiatric treatment. Part 3 is concerned with the influence of psychoanalysis on allied fields. It includes articles on medicine, social anthropology, clinical psychology, animal psychology, and current thought. The book is intended not for the lay public but as a reference book for psychiatrists, psychoanalysts, physicians who are interested in the principles of psychodynamics, psychologists, and social scientists. It is a scholarly and comprehensive presentation, skillfully prepared and edited, which includes a wealth of information that is not contained elsewhere in one volume. The authors have given almost 1,000 references. They have rendered a real service by their respective contributions.

Manic-Depressive Psychosis and Allied Conditions. By Leopold Bellak, M.D., Clinical Assistant Professor of Psychiatry, New York Medical College, New York, with Blaise Pasquarelli, M.D., Research Associate, New York State Psychiatric Institute, New York, Ernest Parkes, M.A., Instructor in Psychology, New York University, New York, Sonya Sorel Bellak, and the collaboration of Sydell Braverman, M.A. Foreword by Winfred Overholser, M.D. Cloth. $9.75. Pp. 306. Grune & Stratton, Inc., 381 Fourth Ave., New York 16, 1952.

This book summarizes the literature on manic-depressive psychosis and related disorders, much of which is considered by the authors as not being readily or easily available to psychiatrists. The work was, in part, sponsored by a grant from the National Institute of Mental Health of the United States Public Health Service. The authors mention more than 1,000 studies of affective disorders and provide adequate bibliographic reference to them with the stated purpose of providing an incentive to further work in this field rather than the presentation of a critical review.

The book is divided into two parts. The first part discusses diagnosis, treatment, and prognosis of manic-depressive psychosis, and the second part relates to allied conditions, such as involutional psychosis, reactive depression, depression of old age, and psychotic reactions to pregnancy. Additionally, the author discusses his own multiple-factor psychosomatic theory of manic-depressive psychosis and relates it to a parallel theory of causation in schizophrenia. The summary of the literature will be important to those interested in research, as it cites, in brief form, the statements that have been made by previous investigators of the affective disorders. From this point of view, the volume makes a contribution of considerable value.

The Thoracic Surgical Patient—Preoperative, Anesthetic and Postoperative Care. By Lew A. Hochberg, M.D. Foreword by Frank B. Berry, M.D. Cloth. $8.75. Pp. 364. Grune & Stratton, Inc., 381 Fourth Ave., New York 16, 1952.

This book has been written in the main by Hochberg; however, six other specialists have collaborated in writing specific sections of the book. Some of the chapters are repetitive; however, this is no drawback and in some instances accentuates some necessary points and procedures. Some might disagree with certain statements made, but the basic teachings and precepts are well presented and should go far to produce good results. The emphasis upon such ofttimes neglected subjects as anesthesia, nutrition, fluid balance, blood replacement, resuscitation, and rehabilitation makes this work worthwhile. The section dealing with physiology and pathological physiology is particularly well done.

It is regrettable that illustrations are lacking since there are numerous opportunities in this book to have used simple line drawings; these might have emphasized numerous points.

The quality of the paper could have been improved on. The book can be recommended for both undergraduates and postgraduates interested in thoracic surgical patients.

As bases anátomo-patológicas da neuríatria e psiquiatria. Volumes I e II. Por Walter Edgard Maffei, D.M., Livre-docente de anatomia patológica, patologista do Hospital Juquerí (Franco da Rocha, Est. S. Paulo). Cloth. Pp. 491, with 345 illustrations; 494, with 410 illustrations. Imprensa Metodista, Rua da Liberdade 659, São Paulo, 1951.

The author, a distinguished neuropathologist from the University of São Paulo and its associated hospitals, is fully qualified to write on the subject of the pathological changes in the nervous system resulting from injury, disease, and developmental anomalies. His material, based on 16,000 autopsies, is abundant, and his laboratory facilities are excellent. The book covers the usual topics of degenerations, inflammations, disorders of circulation, with long chapters on syphilis, tumors, peripheral nervous disease, meningitis, trauma, and parasitic infections. An alphabetical index is provided, but only a few references to the literature are included as footnotes, without a complete bibliography. Over

---

The reviews here published have been prepared by competent authorities and do not represent the opinions of any official bodies unless specifically stated.

800 well-produced illustrations greatly add to the value of the text, particularly for those readers who cannot read Spanish fluently. As the author was trained in France, his background is frequently reflected by references to French literature.

The volumes, well bound and serviceable, are printed with care on good paper. They are a splendid contribution to the subject, of special value to physicians in North America because of the abundant illustrations, the diagrams drawn by the author, the sections on parasitic diseases, and the scholarly text. This monograph should be in all pathology laboratories and medical libraries.

The Welfare State and the National Welfare: A Symposium on Some of the Threatening Tendencies of Our Times. Edited, with introduction, by Sheldon Glueck, Roscoe Pound Professor of Law, Harvard Law School, Cambridge. Cloth. $3.50. Pp. 289. Addison-Wesley Press, Inc., Kendall Sq., Cambridge 42, Mass., 1952.

National social and economic policy has been the subject of contemplation by persons of all nations since the beginning of time. Never before in the history of the United States has it been so important to decide not only which road we will take but how far down that road we will go. A symposium of addresses and articles dealing with some of the more questionable politico-economic trends in the last decade has been compiled and edited, with an introduction by Sheldon Glueck, under the title "The Welfare State and the National Welfare." The contributing authors, statesmen, educators, lawyers, engineers, economists, and journalists, are men from both sides of the political fence who are compelled by their feeling of public responsibility to raise their voices in protest. The book includes articles by Bernard Baruch, Vannevar Bush, Harry F. Byrd, Donald K. David, John Foster Dulles, Dwight D. Eisenhower, Herbert Hoover, Raymond Moley, Edwin G. Nourse, Roscoe Pound, Donald Richberg, Walter E. Spahr, and the editors of *Life*. While each has a different emphasis, all agree that unless some reasonable and clear limits are placed on the conception of what the general welfare is and to what extent our financial future can be mortgaged to carry out this illusion of security we are in grave danger of national bankruptcy. National bankruptcy is just a symptom of the disease that is eating away at the American heritage and will continue to spread if we are willing to legislate away our personal liberties for a feeling of false security and propel ourselves down the road to a welfare state.

Are we losing any liberties? Let us figure it out in dollars and cents. Taxes and federal expenditures took $31.60 from every man, woman, and child in 1929. This amount increased to $268.23 per person in 1948 and in the face of proposed increases could easily amount to nearly $500.00 in 1952. If we add state and local taxes to federal taxes, the annual tax obligation of the American public would be more than 40 cents out of every dollar they earn. Where is the savings or surplus that starts businesses, builds churches, and finances education and retirement. There is none. In the face of these social necessities the welfare state steps in to do it for us, and these are then under the control of the government. The welfare state simply offers to do for us what we can do better, more cheaply, and with greater satisfaction for ourselves. What becomes of our freedom when it is decided for us where, how much, and by whom our money will be spent?

It is a delusion to think that we can buy security and can still retain our liberties simply by paying high taxes. There can be no security for persons whose livelihood depends on political favor and political pressure. In order to have an effective planned or welfare state there must be control of the factors of production by the planners, in this case the government, and this is the very definition of national socialism. As Richberg states, ". . . a comprehensive welfare state must be a police state."

It is the use of so-called democratic methods to achieve inroads to a planned economy that deceives and confuses public opinion. Ambiguous wording in campaigns of special interest groups paint beautiful pictures, but when the paint dries we find we have mortgaged our personal liberties for a controlled state. During this year of national elections, we have a chance to decide if the present trend should continue. We must individually and collectively look beyond special, regional, or personal interests and see where we want to go. America must choose.

Medical Nursing. By Amy Frances Brown, R.N., M.S. in N., Associate Professor of Medical Nursing, State University of Iowa College of Nursing, Iowa City. Second edition. Cloth. $5.50. Pp. 1099, with 387 illustrations. W. B. Saunders Company, 218 W. Washington Sq., Philadelphia 5; 7 Grape St., Shaftesbury Ave., London, W.C.2, 1952.

This second edition, like the first, is intended to enable the student nurse to give more effective and complete care to medical patients. The author has had wide experience as an educator in the field of medical nursing. In this edition, new chapters have been added on poliomyelitis, viral hepatitis, convalescence, rehabilitation, radiological nursing, and anti-infectious agents. The features that characterized the first edition have been given greater emphasis in this edition. Stress is on nursing care, the consideration of the patient as an individual and his need for total care, the problem of the chronically ill and aged, the teaching of patients, the integration of pharmacology, and the selection of appropriate illustrations. Attention has been given to sociologic, economic, and emotional factors as they affect the health picture of individuals or groups.

The book is divided into 11 units that include diseases of the respiratory system, the cardiovascular-renal system, the digestive system, the skin, the endocrine system and metabolism, and the nervous system. There are also sections on nutritional deficiency disease, the arthritides, allergy, and communicable disease. The illustrations consist of photographs, some in color, and diagrams, charts, and graphs. All chapters are followed by a bibliography.

This is a comprehensive text. Modern diagnosis and treatment are clearly and concisely discussed to a degree that will enable the student to develop an understanding of them as a basis for nursing care. Emphasis is, however, placed on the role of the nurse in patient care. This approach is logical and practical and does much to make this text useful for student nurses.

Attaining Manhood: A Doctor Talks to Boys About Sex. By George W. Corner, M.D., Director, Department of Embryology, Carnegie Institution of Washington, Washington, D. C. Second edition. Cloth. $1.50. Pp. 97, with 16 illustrations. Harper & Brothers, 49 E. 33rd St., New York 16, 1952.

Attaining Womanhood: A Doctor Talks to Girls About Sex. By George W. Corner, M.D., Director, Department of Embryology, Carnegie Institution of Washington, Washington, D. C. Second edition. Cloth. $1.50. Pp. 112, with 15 illustrations. Harper & Brothers, 49 E. 33rd St., New York 16, 1952.

Referred to as companion volumes, these book follow essentially the same pattern of presentation. Each consists of eight chapters, and topics common to both books are the human reproduction system, attainment of maturity, sex attraction, sex conduct, and the scientific study of sex and reproduction. In the volume for boys, the chapter dealing with venereal diseases is called sex disorders, whereas a similar chapter in the book for girls is simply designated as venereal disease. As the author points out, either volume would provide satisfactorily basic information for either sex, but there is good reason for avoiding a composite publication. The books are written in a frank, friendly style without any pompous warnings, and explanations are simple yet entirely adequate. A point on which the author should be commended is his use of correct terms, preferring, as he says, to depend on the intelligence of his readers in discussions in which simpler language would not be accurate. Both volumes are adequately provided with instructive illustrations; there are 15 in the book for girls and 16 in the book for boys. These publications can be recommended to high school students; they would undoubtedly also be of considerable value to many parents whose background of information in this field is hazy or incomplete.

Good Food and Bad Stomachs: 500 Delicious and Nutritional Recipes for Sufferers from Ulcers and Other Digestive Disturbances. By Sara M. Jordan, M.D., and Sheila Hibben. With introduction by Harold W. Ross. Cloth. $2.95. Pp. 255. Doubleday & Company, Inc., Garden City, New York, 1951.

This is a useful and encouraging book of recipes and directions for preparing foods for patients with peptic ulcers and those who have other gastrointestinal disturbances requiring a bland and nonirritating diet. Aside from its thoroughly scientific character and complete reliability, it possesses a virtue by no means common in dietetic cookbooks; namely, it places emphasis on the attractiveness of the diet.

Text-Book of Orthopædic Medicine. Volume II: Treatment by Manipulation and Deep Massage. By James Cyriax, M.D., B.Ch., Physician to Department of Physical Medicine, St. Thomas's Hospital, London. Fourth edition. Cloth. $6. Pp. 335, with 121 illustrations. Paul B. Hoeber, Inc., (medical book department of Harper & Brothers), 49 E. 33rd St., New York 16, 1951.

The text is extremely well illustrated and discusses methods of massage and manipulation and their usefulness in a vast number of conditions pertaining particularly to the musculoskeletal system. Although some techniques of massage and manipulation that are acceptable are discussed, it is difficult to understand why a textbook of orthopedic medicine contains sections on manual vibrations for affecting the pylorus, duodenum, ascending colon, descending colon, and distention of the stomach. Another technique directed toward reproducing "fixed subluxation of the sacroiliac joint" will not be too well received by those who question the existence of such a condition.

The text seems to be overenthusiastic in its indication of the value of massage and manipulation, but, in spite of this, it does clearly present various techniques for the treatment of parts of the musculoskeletal system. The book appears to be written especially for physical therapists.

Map of the World Distribution of Malaria Vectors. By Jacques M. May. Reprinted from Geographical Review. Volume XLI, no. 4, 1951. Paper. Pp. 638-639. American Geographical Society, Broadway at 156th St., New York 32, 1951.

Map of the World Distribution of Cholera. By Jacques M. May. Reprinted from Geographical Review, Volume XLI, no. 2, 1951. Paper. Pp. 272-273. American Geographical Society, Broadway at 156th St., New York 32, 1951.

Map of the World Distribution of Poliomyelitis. By Jacques M. May. Reprinted from Geographical Review. Volume XL, no. 4, 1950. Paper. Pp. 646-648. American Geographical Society, Broadway at 156th St., New York 32, 1950.

These maps form part of a projected "Atlas of Diseases" instituted by the American Geographical Society, a professional organization of geographers that is especially interested in medical geography. The first map, prepared with the assistance of a grant from the National Foundation for Infantile Paralysis, includes data on morbidity rates for poliomyelitis since 1900, regional differences in the age group predominantly attacked, epidemics among military personnel, and percentage of positive reactions to neutralization tests in selected areas. The sources of information are appended. The second map shows the world distribution of the various types of malaria parasites and of the mosquito vectors. Also included are brief notes on the epidemiology of malaria, a résumé on the natural history of the vectors, and a selected bibliography. The third map shows the endemic foci of cholera, the routes of spread of the first four pandemics of cholera, the outbreaks of cholera between 1923 and 1950, monthly occurrences of cholera in India, and the 1947 Egyptian epidemic.

This series of maps should be of great interest to teachers and students of epidemiology and to all others wishing information concerning the incidence of important diseases in various parts of the world.

Fluid Balance: A Clinical Manual. By Carl A. Moyer, M.D., Professor of Surgery, Washington University School of Medicine, St. Louis. Cloth. $3.75. Pp. 191, with 1 illustration. Year Book Publishers, Inc., 200 E. Illinois St., Chicago 11, 1952.

This manual is described by the author as a practical guide to fluid and electrolyte imbalances, with their changes of volume and composition of the body fluids and the symptoms and signs that they produce. The subject is concisely reviewed. Clear-cut descriptions of many problems of electrolyte and water imbalance are discussed in brief form.

The subject is covered by the author from a primarily surgical viewpoint. Emphasis is placed on postoperative complications. Some medical conditions with outstanding problems of fluid balance are mentioned in passing. The changes in extracellular fluid volume and composition are described and illustrated by reports of cases. Some original and useful concepts are included. The coverage of disturbances of ions other than sodium, chloride, and bicarbonate ions is incomplete; an example is the omission of mention of the neuromuscular signs of potassium intoxication. Treatment is clearly outlined and documented by illustrative cases. This should be a useful handbook for the surgeon, but it will be of somewhat less interest to the general physician because of the limited coverage of problems associated with medical disease.

Thomas Jefferson: Scientist. By Edwin T. Martin. Cloth. $4. Pp. 289, with illustrations. Henry Schuman, Inc., Publishers, 20 E. 70th St., New York 21, 1952.

This book is representative of the vast amount of scholarly research on Jefferson that has been going on since his bicentennial in 1943. It provides a fascinating account of a great American president's intellectual curiosity, which brought him into intimate relation with an extraordinary range of scientific fields: botany, geology, medicine, meteorology, agriculture, architecture, astronomy, chemistry, paleontology, ethnology, exploration, invention, and archeology. In these diverse fields Jefferson's insatiable thirst for knowledge was coupled with the desire that the benefits of science be made available to his fellow men so that their lot might be progressively bettered. But perhaps more important than his search for daily application of scientific knowledge to useful social ends was Jefferson's ardent championship of the freedom of scientific inquiry. He maintained that circumscribing free scientific inquiry could only retard "all advances in science as dangerous innovations." Throughout his long life Jefferson expressed a profound belief in "the illimitable freedom of the human mind." This book is highly recommended.

Kinesiology in Nursing: Laboratory Manual. By Bernice Fash, M.A., University of Illinois. Cook County School of Nursing. McGraw-Hill Series in Nursing, Lucile Petry, consulting editor. Paper. Loose-leaf. $2.80. Pp. 142, with 102 illustrations by Paul H. Stone. McGraw-Hill Book Company, Inc., 330 W. 42nd St., New York 18; Aldwych House, Aldwych, London, W.C.2, 1952.

In this book, a detailed application of anatomy and physiology to the problems of posture and exercise for patients is discussed. The author has considered these problems from both viewpoints, namely that of the patient in danger of weakness, deformities, and bedsores and that of the nurse confronted with the equally real dangers of disabling overstrain. The illustrations, which at first strike the reader as unconventional, are soon appreciated as remarkably illuminating; they make the book extremely valuable. It is hoped that in some future edition the author will break further with convention by getting rid of the illogical adjectives "concentric" and "accentric" as applied to certain kinds of muscular activity (page 9). This book should be available in the library of every school of medicine and nursing.

Introduzione alla biometria. Di G. Barbensi, Ars medica, collana diretta dal Prof. Vincenzo Lapiccirella. Cloth. 3000 lire. Pp. 418, with illustrations. Vallecchi editore, Viale dei Mille, 90, Florence, 1952.

The author undertakes to present to biologists an easy exposition of statistical methods useful in their specialty. Interspersed in the smoothly written text are 133 numerical problems from various fields of biology and medicine. Author and publisher have cooperated in producing a remarkably legible book in which one readily finds most of the concepts that have become familiar in current textbooks: probability, graphic representation, measures of central tendency and of dispersion, asymmetry and kurtosis, correlation and contingency, interpolation, regression, and variance and covariance. There are useful tables, a brief bibliography that does justice to foreign publications, an index, and a table of contents.

The book is written more for the observer than for the experimenter, with examples chosen more from anthropometry than from experimental therapeutics. As a result there is little emphasis on the important idea of the contratest, contre-essai, or control, an idea that will require much further emphasizing before it is sufficiently appreciated in clinical research. This deficiency can easily be remedied in future editions, which are to be anticipated in view of the general excellence of this book.

QUERIES AND MINOR NOTES

REMOVAL OF TRACHEOTOMY TUBES

To the Editor:—*In a hospital there is a difference of opinion regarding the proper time to attempt extubation following tracheotomy done for acute nondiphtheritic laryngitis and regarding the procedure to be followed. What is your opinion?*

M.D., Pennsylvania.

This inquiry was referred to two consultants, whose respective replies follow.—Ed.

Answer.—It seems obvious that a tracheotomy tube should be left in place as long as it is required; however, the decision concerning when to remove it usually rests with the operator. In acute conditions, when tracheotomy is indicated, there is generally edema about the glottis. Under such circumstances, the edema subsides with appropriate treatment, as a rule, within a few days, and the tube can be withdrawn at the end of a week or 10 days at the most. A common fallacious practice among residents training in their specialties is to gradually block off the mouth of the tube with adhesive tape or by other means to determine if the patient has a free airway. If the tube happens to fit snugly into the trachea, complete blocking of its protruding end should cause asphyxiation of the patient. If the patient continues to breath it is only because the tube is small enough to permit air to pass along its sides into the lungs. Even under the latter condition the physician is demanding that there be normal breathing with a foreign body (tracheotomy tube) in the respiratory tract. At one time, tracheotomy tubes with a "window" in the shoulder were frequently used. With such a tube, blocking of the external orifice would indicate properly whether there was a free passage of air through the glottis and the tube into the lungs. In some cases of laryngotracheobronchitis and in bulbar poliomyelitis there may be profuse secretions that require frequent aspiration for a considerable time. As a consequence, it may be desirable to leave the tube in place much longer than for most acute infections. Nevertheless, the tube should be removed as soon as this can be done with safety. Cases have been observed in which it was necessary for the patient to use a tracheotomy tube for many years after the acute infection had subsided.

The presence or absence of edema about the glottis can be determined by palpation. It is sometimes advisable to make such an examination before removal of the tube, although inspection with a laryngoscope is generally preferred. After removal of the tube a piece of sterile gauze may be laid over the opening until it becomes apparent that a reinsertion of the tube will not be necessary. The skin surfaces often can be approximated with adhesive tape instead of sutures. The wound heals rapidly.

Answer.—No positive time interval can be established for extubation following tracheotomy for any cause. In acute nondiphtheritic laryngitis, tracheotomy is done to pipe air into the trachea below an obstructed larynx and the tube can be removed only after the obstructing edema and inflammation subsides. This may take 2 or 3 days or a week to 10 days. It is usually more difficult to extubate small infants than older persons, because slight, persisting edema in a small infant causes a high degree of airway obstruction, whereas the same persisting edema in the larynx of an older person will cause a relatively small degree of obstruction.

Several extubation procedures are available. The simplest is to reduce the size of the tracheotomy tube during the daily changes of the tube after the third or fourth day; for example, if the patient was tracheotomized with a no. 2 tube, the tube size should not be changed until toxemia subsides and the temperature and condition of the chest are normal, which, in acute nondiphtheritic laryngitis, usually occur after the third to the seventh day. Then a no. 1 tube should be substituted for the no. 2 and on the next day a no. 0 tube for the no. 1, provided there is no return of obstructive symptoms. Finally, the small tube may be corked with a partial or complete rubber cork or the inner tube may be closed with an adhesive tape cover to encourage resumption of mouth breathing. In the meantime, the fistulous tract for reinsertion of the tube in case the airway is not yet adequate is maintained. If the patient can sleep through the night with the tube plugged, the tube may be removed and the fistula will usually close spontaneously. Close observation of the patient is necessary during this time so that the airway may be reopened, if necessary, by removing the rubber cork or the adhesive tape covering the inner tube. Another technique is to substitute a small diameter blind extubation plug for the tracheotomy tube for a 24 hour test period after the acute process has subsided, thus maintaining the tracheostomy while reestablishing mouth breathing.

MEPHENESIN CONTRAINDICATED IN NERVOUS DRIVERS

To the Editor:—*A professional driving instructor is confronted with a large number of nervous students. Many of these students have acute symptoms, with noticeable tremors and increase in tension, at the time of their examination by the motor vehicle department for a driver's license. Would mephenesin be useful in decreasing the nervous tension and thus improving the driving of these students at the time of examination? What dangers, if any, would be involved in its use?* *John H. Kennard, M.D., Manchester, N. H.*

Answer.—Mephenesin was introduced by Berger and Bradley, in 1946, as a drug capable of producing muscular relaxation without loss of consciousness. Kaada's studies showed the site of action of the drug to be the internuncial neurons of complex polysynaptic circuits. Gammon and Churchill have shown that there is also depression of subcortical and cortical activity. The drug has been used in a variety of clinical syndromes with varying degrees of success. It has been noted to reduce tremors and to produce a sedative effect in certain cases. The drug is not, however, without side-effects; the most frequently observed have been sleepiness and dizziness. Laurence has also reported temporary collapse, fecal incontinence, and vomiting following ingestion of the drug. It would appear, therefore, that while some of the described symptoms might be alleviated by this drug, the side effects would contraindicate its use by anyone driving an automobile.

PERIODIC DIARRHEA

To the Editor:—*A patient has had repeated episodes of diarrhea, which are apparently caused by Endolimax nana infection. The patient has received aureomycin and several courses of diiodohydroxyquinoline (diodoquin®), with no permanent cure resulting. Inevitably, the cysts of the organism reappear in one to three months. I would appreciate suggestions regarding treatment.*

M.D., Illinois.

Answer.—Endolimax nana is not generally considered to be a pathogen, and one should be cautious about attributing gastrointestinal symptoms to this parasite. It is commonly found in routine examination of stool specimens. If thorough gastrointestinal studies, including a complete roentgenographic series, gastric analysis, and proctosigmoidoscopy as well as examination of the stools for fat content and muscle fibers, do not reveal a demonstrable organic cause for the diarrhea, psychogenic factors should be considered in the diagnosis of relapsing or periodic diarrhea.

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any official bodies unless specifically stated in the reply. Anonymous communications and queries on postal cards cannot be answered. Every letter must contain the writer's name and address, but these will be omitted on request.

REDUCING DIET FOR HYPOGLYCEMIC PATIENTS

To the Editor:—*Please outline a reducing diet for a patient with hypoglycemia.* F. H. Corpening, M.D., Horse Shoe, N. C.

Answer.—The diet for an overweight patient with hyperinsulinism (spontaneous hypoglycemia) differs little from the low-calorie (1,250 calories) reducing diets generally prescribed by physicians. It should be low in carbohydrates and high in proteins, with a limited amount of fats. The ingested food should be divided into three small meals a day, an egg for breakfast, fish or other seafood, or cheese and crackers for lunch, and lean meat in liberal quantities for dinner. An abundance of vegetables containing 3 or 5% carbohydrate may be eaten for lunch and dinner. Fruit or fruit juices (orange, apple, or grapefruit) should be taken for breakfast, every two or three hours between meals, at bedtime, and, if awake, during the night.

The following diet has been used successfully in many overweight hyperinsulin patients:

Breakfast.—One fruit: half a grapefruit, an orange, or orange juice, half of a cantaloupe, peaches, or any other fruit in season, without sugar; one egg, cooked any way except fried; one slice of whole wheat bread toast; one pat of butter; and one cup of coffee without sugar if one usually drinks coffee.

Dinner.—Soup: cold or jellied chicken or beef consomme or tomato juice. Green vegetables (one or two varieties): large serving of spinach, turnip greens, mustard greens, tender string beans, cabbage, squash, egg plant, okra, carrots, cauliflower, brussels sprouts, or onions, cooked without grease. Lemon juice may be used freely on vegetables after they have been cooked.

Meat: a large portion of chicken, turkey, mutton, roast beef, tender steak, thinly sliced boiled ham, or fish, cooked without much grease. Trim fats from meats. Bread: one slice of whole wheat bread, dry toast, a small piece of country-ground corn meal bread, or one small corn muffin.

Dessert: peaches, baked apple, or other fruit or berries with milk but no sugar, cantaloupe, a small piece watermelon, or other fruit desserts.

Luncheon or Supper.—Fish, shrimp or other seafood, or any cheese. Fruit or uncooked vegetable: large serving of lettuce, cole slaw, tomato, grapefruit, or waldorf salad. French dressing may be used. Celery and radishes. Bread: one slice of whole wheat bread or toast, and one pat of butter. A glass of buttermilk or skimmed milk. Dessert: an orange, cantaloupe, baked apple without sugar, or other fresh fruit desserts without sugar may be eaten.

Regulating the life of the hyperinsulin patient is important. He should be particularly careful to avoid fatigue and requires rest in bed eight or nine hours at night and from half an hour to an hour after the noon meal. He should drink not more than one cup of coffee a day. It is particularly important to eliminate sweets and cane sugar products of all kinds, since they stimulate the secretion of insulin and are, therefore, harmful. The cola-caffeine containing soft drinks are an important cause of hyperinsulinism and should be eliminated entirely. Beer and all other alcoholic beverages, when used regularly or in excessive amounts, because of their effect on the liver, cause spontaneous hypoglycemia (relative hyperinsulinism). Total abstinence is advisable in all cases of hyperinsulinism.

INFECTIOUS HEPATITIS AND PREGNANCY

To the Editor:—*Is a therapeutic abortion indicated in a woman who is five months pregnant and has severe infectious hepatitis? She is doing well clinically, and her serum bilirubin has steadily declined from 12 mg. per 100 cc. to 2 mg.*

M.D., Tennessee.

Answer.—The only consideration is whether the hepatitis is severe enough to indicate abortion. Since this patient is improving, abortion does not appear indicated. There are apparently no reports of the disease affecting the offspring in utero. In general, if the patient is in good condition and on a high protein diet, there should be no undue strain on the liver. More rest, however, is required, and a considerable length of time is necessary for the patient to regain her strength and tolerance to exercise.

DIFFERENCE OF BLOOD PRESSURE IN THE ARMS

To the Editor:—*A man, aged 28, had been turned down for insurance because of hypertension. He has since been insured, because on succeeding occasions his blood pressure was normal. On the day he was found to have hypertension, the pressure was determined on his left arm, whereas it had always been taken on the right arm previously. The reading of his left arm was 160/105 and of the right arm, 128/80. At subsequent examinations, it has been the right arm that is hypertensive, 170/110, and the left arm has given a reading of 130/80. Is there any known cause for this phenomenon? Could it be a one-sided autonomic nervous system imbalance? Gross tests for the scalenus anticus syndrome are negative.*

Robin Smith, M.D., Neenah, Wis.

This inquiry was referred to two consultants, whose respective replies follow.—Ed.

Answer.—Differences in blood pressure in the two arms are frequent enough to warrant routine determinations on both sides. Angulation of or pressure on the aortic branches and the aortic plaques, or partial occlusion may account for differences between the two sides; also, in some patients the first determination of blood pressure yields higher figures than subsequent ones. It is likely that such a patient has increased vasomotor reactivity. He should be watched for the development of a continuous diastolic hypertension.

Answer.—It is probable that this patient consciously or unconsciously is applying pressure to the artery. It would be interesting to measure arterial pressure with the arms at different angles to the body. The suggestion that the blood pressure differences are due to autonomic imbalance seems unlikely.

PAROTITIS AND RHEUMATOID ARTHRITIS

To the Editor:—*A woman, aged 50, has a mixed type of arthritis. One year ago she had a series of 20 gold treatments. On the date of the 20th treatment, painful swelling of both parotid glands developed. The physician who gave her the gold injections told her she had mumps. The glands were so large that they produced facial disfigurement. The patient also complained of dryness of the mouth. No tenderness of the large and firm parotid glands was elicited. There was no history of infection or other glandular disease. The patient was given weekly x-ray treatments of 100 r each directed to each parotid gland through a 6 by 8 cm. port tangentially. Six treatments, a total of 605 r, were given to the left parotid gland, and seven treatments, a total of 705 r, were given to the right parotid gland. There was complete regression of the swelling in both glands and less dryness of the mouth six weeks after the last treatment. Could the gold injections have caused the bilateral chronic parotitis?*

M. L. Pindell, M.D., Beverly Hills, Calif.

Answer.—This consultant has never known disease of the parotid glands to develop as a consequence to or complication of gold therapy or rheumatoid arthritis. It is highly possible that this patient had inflammation of the parotid glands as one of the infrequent nonarticular disorders seen in patients with rheumatoid arthritis. Such disease of the salivary and lacrimal glands has been described by Sjogren and is sometimes referred to as Sjogren's disease. It is described in a recent article by Reader and co-workers (*Ann. Rheumat. Dis.* **10**:288 [Sept.] 1951).

SEROUS DISCHARGE FROM THE NIPPLES

To the Editor:—*In* The Journal *April 5, 1952 (page 1261), a query concerning a 34-year-old woman who has had at intervals a serous discharge from the nipples makes no mention of whether she has had any pregnancies. Occasionally, women who have had pregnancies show, in later years, a discharge from one or both nipples, which is nonsanguineous and in which no malignant cells can be recognized or other abnormal cytological condition detected.*

Luther M. Boyers, M.D.
2105 Center St., Berkeley 4, Calif.

AIRWAY MANAGEMENT IN PATIENTS WITH POLIOMYELITIS

ELECTIVE TRACHEOTOMY AND TRACHEAL INTUBATION

Hamilton S. Davis, M.D.
and
Harold F. Bishop, M.D., Valhalla, N. Y.

There is controversy, at present, concerning the place of early (so-called elective or prophylactic) tracheotomy in the supportive treatment of acute anterior poliomyelitis with severe respiratory involvement. Those who oppose its use, exemplified in the literature by Stimson [1] and Sweet,[2] claim comparable results with conservative treatment, with tracheotomy used as a last resort. Galloway,[3] Weiland,[4] Brown and associates,[5] and West and Bower,[6] on the other hand, favor it as the most effective means of combating obstruction of the airway by secretions and vocal cord palsy. It would appear the trend in recent years has been toward the latter approach, particularly in the larger poliomyelitis centers.

It seems apparent that two phases of the problem exist. Initially, the patient must be protected from early asphyxial death resulting from high respiratory tract obstruction, pulmonary edema, and hypoventilation. Later, lower respiratory tract obstruction with its subsequent atelectasis and pneumonitis, which is the frequent sequel to hypoventilation and inability to cough, must be combated. Practically all who die after surviving the initial phase do so because of pulmonary complications, in spite of antibiotic therapy.

It would seem, therefore, the treatment of choice would be that which coped most effectively with both phases. Unfortunately, reports to date have dealt predominantly with the primary disease process, describing only in a general way the morbidity and mortality arising from pulmonary complications. Such data must be reported carefully, for only by its accumulation can some answer be reached regarding effective therapy. There are so many variables that a controlled study is almost impossible; the only hope seems to lie in the accumulation of enough clinical and pathological data to permit a relatively objective conclusion.

Because of several factors, there was a swing from conservative management, at our hospital, to the use of the early tracheotomy. First, the conservative method had left much to be desired, there having been patients thus treated who, in retrospect, might have fared better with early tracheotomy. Second, we were favorably impressed with the results of tracheotomies in comatose patients, whose respiratory problems simulate those of patients with poliomyelitis. Third, we felt that the writers stressing this method presented rather convincing logic. Also, the virulence of the disease in 1949, with its high incidence of severe bulbar forms, influenced our decisions. To cope with this entire problem, a "poliomyelitis team," of which the anesthesiologist was a member, was formed. The resuscitative features presented in handling these patients, many of whom were children, led to the development of a technique that has not, to our knowledge, been reported elsewhere in the English literature. Certain aspects of this technique are original; however, it must be pointed out that many features in the over-all plan have been borrowed from the works of Galloway,[3] Brown and co-workers,[5] and Leigh and Belton.[7] The purpose of this discussion, then, is twofold: to present a treatment plan based on the use of early tracheotomies in patients with poliomyelitis and to give the results, with emphasis being placed on morbidity due to respiratory involvement as well as mortality.

From the Department of Anesthesiology, Grasslands Hospital.

DEFINITIONS

It is appropriate, at this time, to list certain definitions as we have employed them in our study.

Disease Classification.—Three types of acute poliomyelitis have been recognized in our series of cases: spinal, bulbar, and bulbospinal. "Encephalitic" manifestations have been deliberately excluded because of their questionable clinical differentiation, in most instances, from hypoxic reactions. That there is actual invasion of the cerebral hemispheres by the disease process in certain cases has been demonstrated pathologically by Brown and co-workers[5] and Bodian[8] and in our own material. However, whether such minimal involvement as has been described in these regions is of clinical significance is debatable. There were no so-called pure encephalitic forms in this series.

1. Spinal Type: This type indicated involvement of spinal nerves only, as determined clinically. All patients coming to autopsy revealed involvement of higher centers; the diagnosis of spinal type was, of necessity, a clinical diagnosis only.

2. Bulbar Type: This type indicated involvement of medullary centers and cranial nerves only, as determined clinically or pathologically.

3. Bulbospinal Type: This type indicated involvement of medullary centers, cranial nerves, and spinal nerves, in combinations, as determined clinically or pathologically. This type predominated.

Pulmonary Complication.—The diagnosis of pulmonary complication was made whenever clinical, roentgenographic, or pathological findings indicated significant involvement of the lung parenchyma. Included also was severe tracheobronchial disease; not included were minor degrees of tracheobronchitis associated with the expected trauma of the tracheotomy tube and the frequent tracheal suctioning. For the sake of this study, borderline conditions were considered as pulmonary complications; the figures presented are, therefore, maximum.

TREATMENT

Our treatment schedule may be divided into three periods for the sake of description: the evaluation period, the anesthesia-operative period, and the postoperative period.

Evaluation Period.—When a patient has respiratory dysfunction, whether it be spinal or bulbar in origin, he is observed closely by the poliomyelitis team. This team is composed of appropriate representatives of the medical or pediatric, neurology, otolaryngology, and anesthesiology services. In the evaluation period conservative measures of positioning, suctioning, oxygenation, hydration, administration of antibiotics, and proper nutrition are practiced by special nurses. During this time, the patient is examined frequently for progressing disease; it is emphasized that respiratory failure represents a concrete danger, whereas the "fatigue" secondary to such examinations is largely hypothetical. If the team decides the patient is becoming worse with conservative therapy, a tracheotomy is performed in the operating room. After this, he is placed in the respirator, if indicated. Indications for tracheotomy and use of the respirator are similar to those first outlined in 1943 by Galloway[9] and emphasized by others since. This is, by choice, an elective procedure. The "last-ditch" or "stab" tracheotomy is mentioned only to condemn it, or, at best, to relegate it to emergency conditions in the field in which proper equipment and personnel may not be available.

Anesthesia-Operative Period.—When the team decides that tracheotomy is advisable, a belladonna drug is given to facilitate the subsequent intubation of the trachea. Sedation is not necessary in these cases and may be dangerous. The anesthesiologist decides whether the patient is in immediate need of oxygen only, of a patent airway, or both. If he shows minimal obstruction and is getting along reasonably well with nasal administration of oxygen, he is transported to the operating room with oxygen.

With airway obstruction in a conscious patient, endotracheal intubation is accomplished on the ward with topical anesthesia, 10% cocaine being carefully applied to the pyriform fossa bilaterally through pledgets on curved laryngeal forceps. Only minimal anesthesia is necessary in most cases, because of the diminished gag reflex. It is imperative that a good source of suction be available during this time, because of the hypersecretion present. Tracheal intubation under direct laryngoscopy is preferable to the blind nasal method, as the latter frequently necessitates several attempts, thus increasing the possibilities of trauma and hypoxia. The curved MacIntosh laryngoscope blade has proved the most effective for these intubations. Magill endotracheal forceps for directing the catheter should always be at hand.

In those semiconscious or unconscious patients who need rapid resuscitation, it is neither necessary nor advisable to waste time with cocainization; intubation is carried out as quickly as possible and is not infrequently lifesaving. The nasotracheal route, with direct laryngoscopy, is useful on the ward, as the tube is less likely to become dislodged while the patient is en route to the operating room than if orotracheal intubation is used. The airway thus assured, there is almost always spontaneous improvement in the condition of the patient, often with a return to consciousness. The endotracheal tube is well tolerated without further anesthesia, although "bucking" is always present with suctioning attempts down as deep as the carina. If necessary, respirations are compensated by manual pressure on the breathing bag of a closed to and fro carbon dioxide absorption system connected to a source of oxygen. The danger of asphyxia now past, the patient is taken safely to the operating room on a stretcher equipped with oxygen and capable of being placed in the head-down position, the latter facilitating removal of secretions and vomitus.

Tracheotomies have long been done with local anesthesia with or without a bronchoscope in the trachea. It is felt this is not the safest procedure in patients who, by the nature of their disease, have reduced ventilatory capacity. It is our impression that much of the criticism leveled at the use of tracheotomies in these cases stems from the use of this method. Although local anesthesia has undeniable advantages in the proper situation, it can

9. Galloway, T. C.: Tracheotomy in Bulbar Poliomyelitis, J. A. M. A. 123: 1096-1097 (Dec. 25) 1943.

be completely unsatisfactory in terrified, uncooperative patients, especially children. Fear and struggling lead to increased oxygen requirement, trauma with the bronchoscope, and hurried bloody tracheotomies, during which time the circulating epinephrine of the surgeon, as well as the patient, probably reaches considerable levels. For this reason, general anesthesia with the gaseous agents has been adopted in our clinic and has proved satisfactory. Cyclopropane, ethylene, and, on occasion, nitrous oxide are used. These can be applied in such combinations as to provide rapid quiet induction, light maintenance, high oxygen tensions, and almost immediate recovery. They have relatively transient effects on the various organs and are not respiratory tract irritants in the concentrations used.[10] The use of cyclopropane might be objectionable on theoretical grounds in those patients with myocarditis, which is frequently a finding associated with this disease in its severer forms. However, in clinical practice, to date, no ill-effects have been noted, and this gas has been the primary agent in every case. Of interest is the ease of induction and maintenance of anesthesia with minimal amounts of agent in this group of anxious, febrile young patients without premedication other than the use of belladonna drugs. This paradox apparently reflects the altered oxidation processes in the central nervous system in patients with poliomyelitis; it warns against overdosage during the anesthetic management.

In the induction of anesthesia, the breathing bag is filled with oxygen, and then a flow of equal volumes of oxygen and cyclopropane is introduced, usually 500 cc. of each in the adult and smaller volumes in small children, until consciousness is lost. An endotracheal tube is, of course, already in place, having been inserted either on the ward or in the operating room by means of the technique previously described. After induction, a constant flow rate of 5% to 20% cyclopropane with oxygen is maintained, depending on the patient's requirements. A to and fro absorption system has proved to be most adaptable with regard to reduction of dead space and breathing resistance to a minimum, portability features, and ease of sterilization; no doubt a circle absorption method could be adapted satisfactorily. In the subsequent sterilization of the equipment, it might be mentioned here, a dilute formaldehyde solution in alcohol is used for rubber and plastic parts, metal parts being autoclaved.

The surgeon now enters the trachea through a surgical field in which the aim is careful hemostasis. The site of the tracheotomy is, of course, the surgeon's choice. The highest safe tracheotomy, usually through the third tracheal ring, has proved best for subsequent respirator care. At this time the tip of the endotracheal tube is withdrawn just proximal to the tracheal window created. Anesthesia is continued with a high gas flow to compensate for the opening. A mixture of 45% ethylene, 5% cyclopropane, and 50% oxygen is about right, with a total flow of 2 to 5 liters per minute. The trachea is aspirated by the surgeon and the appropriate size of tracheotomy tube inserted. A thin-walled endotracheal catheter, which will fit the tube snugly, is chosen from a previously sterilized set of graduated sizes. The distal end is fitted into the tracheotomy tube by the surgeon; the proximal end is passed through the drape opening to the anesthetist, who attaches it to the canister by means of the usual connectors. Care is exercised to keep dead space minimal. Closed anesthesia is then resumed with a small flow of gasses. One must be careful, at the above stage, not to exert undue positive pressure in the system; mediastinal emphysema could result. It did not occur in this series. The wound is closed in layers and dressed and the flow of anesthetic agent terminated. The patient is awake in a few minutes unless other factors intervene. If he is breathing adequately, he is returned to the ward with oxygen being given through a small catheter in the tracheotomy tube opening. If the respirator is necessary, manually assisted respirations are continued by means of the still attached canister and bag until the patient is placed in the machine.

Postoperative Period.—Survival now depends on two factors: progression of the disease and respiratory complications. At present, we have no control over the former; treatment is directed toward preventing the latter. It has been found that the patients with bulbar disease whose main problem is one of obstructed airway and aspiration, get along well once a free airway is established by means of their tracheotomy. It is felt that with this prophylactic tracheotomy the patient has a greater chance to escape the dangers of aspiration and is offered the best possibilities of vigorous treatment if they do occur. One patient (J. W., table 3) was unquestionably saved from an asphyxial death on two separate occasions during his convalescence, when he vomited and aspirated large quantities of tube feedings. Only prompt evacuation of his tracheobronchial tree by means of a catheter through his tracheotomy and the head-down position saved his life. Equally gratifying was the lack of detectable respiratory complications following these two episodes.

When the respirator enters the picture, the outlook is graver. We have used both cuirass and cylinder type respirators. The former has proved an adjunct to, but not a substitute for, the latter. Its nursing advantages are obvious, but, in our hands, the respiratory exchange has not approached that of the cylinder type. The use of a curved metal brace to push the rubber collar into the machine, leaving the tracheotomy outside and easily accessible, has greatly facilitated care of the airway when the cylinder respirator is used. Such braces are available commercially. In addition, as mentioned previously, a rather high tracheotomy is preferable, so that it is as far outside the collar as possible. Too high tracheotomy is to be avoided, however, because of the danger of subsequent laryngeal stenosis, a formidable complication.

To reduce pulmonary complications in the respirator, it is axiomatic that patent tracheobronchial passages and near normal mucous membranes be maintained. That by-passing the upper respiratory tract disrupts certain important physiological processes cannot be denied. The aim is to lessen this insult so that the advantages outweigh the disadvantages. To this end, the nurses are instructed individually in the essentials of proper care for these patients. This includes the correct method of suctioning the trachea, mouth, and nose; the systematic rotation of the patient through the lateral, Fowler, and Trendelenburg positions; the desired oxygen flow rates and humidification; the appropriate respirator pressures and rates; and the care of the patient's skin. The symptoms and signs of hypoxia are reviewed for them. In short, painstaking attention to detail is taught.

---

[10] Adriani, J.: The Pharmacology of Anesthetic Drugs: A Syllabus for Students and Clinicians, ed. 2, Springfield, Ill., Charles C Thomas, Publisher, 1942, pp. 17-24.

A few points on care of the tracheotomy might be mentioned. The otolaryngologist of the team uses a rather long incision, 3 to 4 cm. in adults, closes the wound in layers, and, therefore, does not remove the outer tube initially in less than 72 hours, thus insuring adequate canalization. Subsequently, it is removed, cleaned, and replaced daily. The inner tube is removed and cleaned at least every three hours. Suctioning through the tracheotomy is done by means of low pressures through sterile, terminal orifice, soft rubber catheters. This is carried out rapidly to avoid marked reductions in arterial blood oxygen saturation.

Bronchoscopy is easily performed through the tracheal stoma, even with the patient in the cylinder respirator; the cuirass respirator facilitates this procedure and has proved valuable in this respect. Bronchoscopic aspiration is used without hesitation and, if necessary, repeatedly, when atelectasis occurs. Pounding the chest at intervals is helpful in dislodging thick secretions. Adequate hydration is an absolute necessity to keep secretions thin; to insure this, intravenous polyethylene catheterizations by cutdown have been used almost routinely during the first 48 hours in the respirator, after which tube feeding is attempted. The use of belladonna-like drugs, at this point, is contraindicated. It may be helpful to administer potassium iodide to liquefy secretions.

Curare type compounds are occasionally of great value in the treatment of patients who exhibit such intercostal muscle spasm as to reduce tidal exchange significantly. Intravenous administration of small repeated doses, of the order of 3 to 6 mg. (1 to 2 cc.) of *d*-tubocurarine hydrochloride, or similar drugs in comparable doses, usually suffices; larger doses may be given without fear of adverse respiratory effects, if necessary, in a tracheotomized patient in the respirator. However, histamine-like reactions on the vascular system may follow the administration of large doses of *d*-tubocurarine, so that caution is advisable. Sedation may be used, when it is felt necessary, at this stage in the management of the patient. It was seldom needed in our series. It is contraindicated in the early stages of the illness as mentioned previously.

Weaning from the respirator is a complex procedure in some patients, requiring the utmost ingenuity on the part of the physician. The psychic factors involved are by far the most important. The patient rapidly acquires a dependency on the machine, which increases as time passes. In general, it has been the policy to get them out, for gradually increasing time intervals, at the earliest possible moment. This may mean within a few hours after entry in some instances. Tracheotomies are closed when the patient no longer depends on the machine or, in cases of bulbar disease, when protective pharyngeal and laryngeal reflexes have returned.

Antibiotics are used freely. It is a well-known fact, however, that their use will not prevent infection in portions of the lung that are not aerating properly and from which secretions cannot drain because of obstruction in the bronchial tree.

Paralyzed excretory functions are supported by the use of bladder catheterization and enemas until normal function is restored. The value of the use of stimulating drugs for these functions is questionable.

RESULTS

There were 229 cases of diagnosed acute poliomyelitis in our hospital during the seasons of 1948 and 1949 (83 cases in 1948 and 146 in 1949). The ratio of males to females over the two-year period was 53% to 47% and that of children to adults 60% to 40%. The latter figures are based on adulthood placed at 12 years for females and 16 years for males. All the patients were white.

In 1948, there were 18 (22%) patients with bulbur disease, the majority of these also having associated spinal paralysis. In addition, one patient had severe intercostal paralysis without bulbar signs. There were, therefore, 19 (23%) seriously ill patients. Six (7%), including one child and five adults, were placed in the respirator (table 1). All six had tracheotomies, two before being placed in the machine and four afterward, because of obvious respiratory problems. No other tracheotomies were performed in 1948.

In the 1948 series, two patients (2.5%) died. Both had bulbospinal disease with pulmonary complications proved at autopsy; both had been placed in the respirator without preceding tracheotomies. Of the four who survived, two had clinical evidence of pulmonary complications at some time during their illness. Therefore, 66% of respirator patients had respiratory complications. It is of interest that the two patients who were forced to remain in the machine over two weeks both survived and that neither showed evidence of pulmonary complications at any time.

In the outbreak in 1949 there were far more virulent characteristics, in addition to almost double the total number of cases. Thirty-nine (27%) had bulbar involvement, the majority associated with spinal paralysis. Five others had severe intercostal paralysis without bulbar signs, which brings the total to 44 seriously ill, or 30%. Fifteen (10%), including six children and nine adults, were placed in the respirator. (tables 2 and 3). All patients who were placed in respirator had tracheotomies, 12 before being placed in the machine and the remaining 3 later. There were, in addition, three tracheotomies performed on patients who did not require the respirator. The total number of patients subjected to tracheotomy in 1949 was 18.

* HD = hospital day; HD 0 = day of admission. † Respirator treatment preceded tracheotomy. ‡ Complete autopsy. § Patient died a few hours after admission; no autopsy.

In the 1949 series, 11 patients (7.5%) died; all had bulbar involvement, the majority with associated spinal paralysis. Eight of the 15 placed in respirators died; seven of these deaths were associated with pulmonary complications. Of the seven respirator patients who survived, three had similar complications. From these figures it is evident that 10 (66%) of the 15 respirator patients had complicating respiratory infections. Of the 18 patients subjected to tracheotomy, 9 (50%) died; in 10 (55%) the disease was complicated by respiratory infections. There were five patients in whom the machine was required for more than two weeks; two died and three lived. Both patients who died had pulmonary complications at autopsy; of the three survivors, two had no evidence of respiratory infection at any time.

Two facts are apparent in these 229 cases. Of the 24 most critically ill, 18 (75%) were females and 16 (66%) were adults. This in spite of the fact that males and children predominated in the series as a whole. As might be expected with the above ratio of seriously ill, of the 13 mortalities (5.7) over the two years, the majority were females and adults; 10 were females and 8 were adults.

Eleven of the 13 patients who died had complete autopsies. Two of these had evidence of major atelectasis; six others showed, in varying degrees, minute atelectatic foci in the peripheral lung fields, lobular pneumonia, and pulmonary congestion and edema that was frequently hemorrhagic. It was believed that, with one or two exceptions, these deaths were due to central nervous system failure, not pulmonary disease. Many were sudden and unexpected in patients who seemed to be getting along not too badly. The commonest sites of nervous system involvement were the spinal cord anterior horn cells, the floor and roof of the fourth ventricle, and the bulbar reticular formation. Generalized hemorrhagic manifestations were present in some of the patients; however, these may have been agonal. Nine of the 11 showed myocarditis of varying degrees.

SUMMARY

Two hundred twenty-nine patients with acute anterior poliomyelitis were admitted to a county hospital during the seasons of 1948 and 1949. The outbreak of 1949 in

hematologic effects. There were no demonstrable beneficial or harmful effects.

Hematology: The hematologic studies included erythrocyte, leukocyte, differential, platelet, reticulocyte, and eosinophil counts; sedimentation rates and hematocrit determinations; and bleeding and coagulation times. These tests were made routinely before the beginning of the treatments, on the day of each treatment, and at the conclusion of the treatment series. Two patients were checked daily for one week after the first treatment; five patients were checked every other day for two weeks; and several were examined at half-hour intervals for one and a half hours, then hourly for four hours following treatment. In three cases blood was removed for study from the tube leading to the irradiation chamber before exposure and again from the tube leading away from the chamber after irradiation. No significant blood changes were revealed by these studies.

Diagnostic Groups: Twelve diagnostic groups of patients with the following conditions were chosen for treatment: 23 with infectious hepatitis, 8 with stasis ulcers, 7 with arthritis, 2 each with acute rheumatic fever, pneumonitis, thrombophlebitis, and acute leukemia, and 1 each with lymphosarcoma, chronic brucellosis, sickle cell anemia with leg ulcers, atypical hemolytic anemia with leg ulcer, and herpes zoster.

TABLE 1.—*Summary of Data in First Study (Fifty-One Patients)*

	No. of Patients	Maximum No. of Treatments per Patient	Minimum No. of Treatments per Patient	Average No. of Treatments per Patient	Maximum Days from First to Last Treatment	Minimum Days from First to Last Treatment	Average Days from First to Last Treatment

Herpes zoster	1	12	..	....	1	..	..

Infectious hepatitis. In the group with infectious hepatitis frequent liver profile studies as well as physical examinations were made. All patients with hepatitis were at bed rest in the hospital during the treatments and received high protein, high vitamin diets. Three volunteered the information that they felt better after the treatments. None was made worse. The liver profiles were checked periodically, and all, including the controls, showed improvement. The group with hepatitis presented an unusual opportunity in a controlled experiment. The patients were chosen from a large group of young men who presumably had the same source of infection, the disease having been spread in the group by the use of unclean, contaminated needles during a "heroin party." One patient of the group with hepatitis received seven treatments in which all the steps of the irradiation procedure were performed, but the shutter was kept closed to exclude the ultraviolet rays from the blood. There was no demonstrable difference.

Stasis ulcers. In the group with stasis ulcers, one patient was at bed rest in the hospital, whereas the others were ambulatory. Four reported subjective improvement and decrease in pain, and in five the ulcers decreased in size during treatment. In the hospitalized patient, the ulcers almost completely healed but recurred when he increased his activity even though the treatments were continued. Five patients eventually discontinued treatment of their own accord.

Acute rheumatic fever. Subjective improvement occurred in both patients with acute rheumatic fever. The sedimentation rate was unaffected in either. Both were at bed rest in the hospital.

Pneumonitis. Neither of the two patients with pneumonitis was in the hospital long enough for evaluation.

Brucellosis. The patient with brucellosis was not clinically benefited, and the treatments were eventually stopped because of complicating hepatitis.

Lymphosarcoma. The case of lymphosarcoma was most instructive and emphasizes the difficulty of clinically evaluating the efficacy of the hemoirradiation method. The patient had a subjective feeling of well-being after almost all treatments but occasionally reported nervousness. This patient received 33 treatments with 10 control irradiations interspersed among them. During these 10, the entire procedure was performed, but the shutter was kept closed in order to exclude the ultraviolet rays from contact with the blood. The patient was never told that from time to time this would be done and assumed that all treatments were similar. Her subjective response to both control and regular treatments was the same. She felt stronger, "more alive," and invigorated by the procedures and was disturbed when they were discontinued. At no time, however, was there any objective evidence of either clinical or hematologic improvement.

Miscellaneous. The patients with sickle cell anemia and leg ulcers, atypical hemolytic anemia with leg ulcers, and herpes zoster showed no improvement.

Summary of First Study: The number of control experiments was deliberately limited, because only positive results needed control and only subjective responses needed evaluation. A general summary of the number of treatments and the duration of the cause of treatments in the several diagnostic groups is given in table 1.

Evaluation of Second Hemoirradiation Project.—In July, 1950, the blood irradiation project was resumed by the Hematology Department of Cook County Hospital. The second series included a total of 17 patients with diagnoses of rheumatoid arthritis (2 patients), thrombophlebitis (1 patient), rheumatic fever (2 patients—one with chorea), and pelvic inflammatory diseases (12 patients).

The total number of treatments was 62, averaging almost 4 per case. Although the number of cases in each group was small, in no one case was any objective improvement noted. Many patients stated that they felt better, regardless of whether the drawn blood was irradiated (table 2).

TABLE 2.—*Summary of Data in Second Study (Seventeen Patients)*

Patient	Age, Yr.	No. of Treatments	Amount of Blood Irradiated, Cc.	Clinical Diagnosis	Remarks
H. T.	59	8	120-200	Thrombophlebitis with ulcer, chronic, 3 yr., acute 1 week; varicose veins	No improvement objectively; lesions continued to weep
B. M.	49	5	100-200	Arthritis, 6 mo.	No improvement subjectively or objectively
F. E.	41	4	200	Arthritis, 2 yr.	Subjective improvement; at no time was there limitation of movement
L. S.	6	7	105	Acute rheumatic fever;* before treatment, systolic and diastolic mitral murmur; enlarged heart; sedimentation rate *30*; heart block (1 degree)	After first treatment sedimentation rate rose to 44; after third, severe nosebleed requiring packing; after fourth, mitral and aortic regurgitation diagnosed; sedimentation rate 30; after sixth, sedimentation rate 38, heart rate 104; after seventh, heart block (1 degree) persisted
M. McC.	8	8	105	Acute rheumatic fever and chorea, 2 weeks	Apical systolic murmur; x-ray: early mitralization; EKG normal; sedimentation rate after first treatment 15, after third 41, after sixth 23; no significant changes in heart sounds or x-ray
M. L.	38	2	150-200	Pelvic inflammatory disease, 1 mo. duration; fibroid uterus	Cramping pain in right lower abdominal quadrant; cervical discharge; no objective improvement
R. S.	32	3	120-150	Pelvic inflammatory disease 1 week's duration	Subjective improvement after first treatment; objectively no change; pain persisted after third treatment
J. D.	33	3	200	Pelvic inflammatory disease 3 weeks' duration	Lower abdominal pain; received sulfonamides 3 days and penicillin once; chills, fever continued; generalized tenderness; Bartholin abscess; acute bilateral salpingitis; blood not irradiated first two treatments (temperature elevated); blood irradiated third time, temperature down to 98 F and increased later in day; septic temperature persisted; operated on for pelvic abscess
L. F.	38	3	200	Pelvic inflammatory disease	Received no antibiotics; pain in abdomen 1 day; adnexae bilateral diffuse induration; blood not irradiated with first treatment, but subjectively and objectively better; subjectively and objectively improved after third treatment; no further vaginal discharge; no other medication
L. H.	34	2	100	Pelvic inflammatory disease and fibroid uterus	Received penicillin once before irradiation and felt better; painless; no objective improvement
L. B.	23	1	200	Chronic pelvic inflammatory disease, exacerbation 8 days, rebound tenderness all quadrants; vaginal discharge	Signed release before final evaluation possible
N. M.	?	1	160	S[illegible] lower abdominal quadrants; Bartholin abscess	Discharged after first treatment; subjectively improved
V. M. J.	*19*	*3*	*200*	Pelvic inflammatory disease	Abdominal cramps, discharge, chills, fever, one day; tenderness in both lower abdominal quadrants; after first treatment severe abdominal pain; *given penicillin* once; 3 days later process subsided; subjective improvement; objectively slightly improved at completion of treatment

CONCLUSIONS

We have concluded that none of our patients derived benefit from the irradiation of blood with the Knott hemo-irradiator. These are at best, however, preliminary results. We do not feel that, on the basis of our observations, definitive conclusions can be drawn. It can, however, be categorically stated that, in both series studied by us, the first of 51 cases and the second of 17, no dramatic clinical or reproducible objective changes, which could be attributed to the irradiation treatments rather than the natural variation in the course of the disease or to psychic effects, could be demonstrated. On the other hand, no adverse effects were noted. A longer and more extensive program of study is warranted before in vivo ultraviolet irradiation of blood can be finally either accepted or rejected.

DEVELOPMENT OF PROTEUS AND PSEUDOMONAS INFECTIONS DURING ANTIBIOTIC THERAPY

Ellard M. Yow, M.D., Houston, Texas

Within recent months antimicrobial agents capable of suppressing the multiplication of almost all of the pathogenic bacteria have been given widespread clinical trial. None of these agents has been effective against all strains of the Pseudomonas (Pyocyaneus)[1] and Proteus group of organisms. As the result of the suppression of other more pathogenic bacteria in the prophylactic or therapeutic use of the antibiotics, these relatively nonpathogenic organisms have frequently been allowed to multiply and have played an active part in the pathogenesis of infectious processes.

It is the purpose of this paper to present examples of infections due to Proteus or Pseudomonas that developed during or following therapy with the commonly used antimicrobial agents. During the past two years 56 patients have been observed with such infections. Their diagnoses are presented in the table and eight illustrative cases are described. The pathogenesis, diagnosis, and treatment of these infections are also discussed.

REPORT OF CASES

Case 1.—A 53-year-old chronic alcoholic was admitted to the hospital because of chills, fever, cough, and chest pain. The symptoms began four days before admission and progressed in spite of penicillin therapy. On physical examination there was evidence of consolidation of the lower lobe of the left lung. The liver was enlarged. On admission the white cell count was 5,250, with a predominance of polymorphonuclear leukocytes showing toxic granulations. Sputum and throat cultures revealed Klebsiella pneumoniae. X-ray studies confirmed the clinical findings of pneumonia of the base of the left lung posteriorly.

The patient was treated (fig. 1) with penicillin, dihydrostreptomycin, aureomycin, and chloramphenicol (chloromycetin®). He gradually improved, and by the fourth day of therapy K. pneumoniae could not be cultured from the sputum, the leukocyte count had risen to 18,650, and his temperature had gradually decreased. On the seventh day the patient appeared somewhat worse. The following day his condition appeared markedly worse, and he became disoriented. At this time, x-ray and physical examination revealed evidence of a spread of the pneumonia in the lower lobe of the left lung as well as involvement of the lower lobe of the right lung. Cultures of the sputum revealed Pseudomonas aeruginosa in pure culture, except for an occasional colony of Candida albicans (Monilia). The patient's condition became progressively worse in spite of an increase in the dose of dihydrostreptomycin.

In vitro sensitivity tests indicated that the strain of Pseudomonas was resistant to penicillin, streptomycin, chloramphenicol, and aureomycin, but inhibited by 1.9 μg per milliliter of polymyxin B. The antibiotics being administered were discontinued as the patient was given polymyxin B intramuscularly in doses of 50 mg. every six hours. Within 48 hours the patient began to improve, and there was gradual subsequent resolution of the pneumonia, decrease of the fever, and reestablishment of the normal flora of the sputum. On the eighth day of polymyxin therapy the dose was reduced to 25 mg. every six hours. The drug was continued for a total of 15 days, during which results of daily examinations of the urine and blood and determinations of blood urea nitrogen and urinary output were normal except for occasional traces of albumin. The patient made an uneventful recovery and has remained well.

Case 2.—A 42-year-old woman who worked as an office supervisor had had diabetes since 1927, but had otherwise been well until December, 1949. During the Christmas holidays of that year she had an acute upper respiratory tract infection complicated by a purulent sinusitis. She was treated with penicillin and irrigations intermittently for a month. On the first of February she developed chills and fever, with urinary frequency and burning. She was found to have pyuria and was treated for two days with aureomycin. She improved and returned to work, but the following day there was a recurrence of symptoms. She responded to aureomycin therapy again but in a few days relapsed. During the next month there were eight episodes of urinary infection, which responded to aureomycin but recurred when it was discontinued. The ninth course of aureomycin failed to control elevation of temperature and urinary symptoms, and the patient was referred to a urologist. She was treated with penicillin and streptomycin with improvement. Three weeks later there was a return of the symptoms, and she was admitted to the hospital.

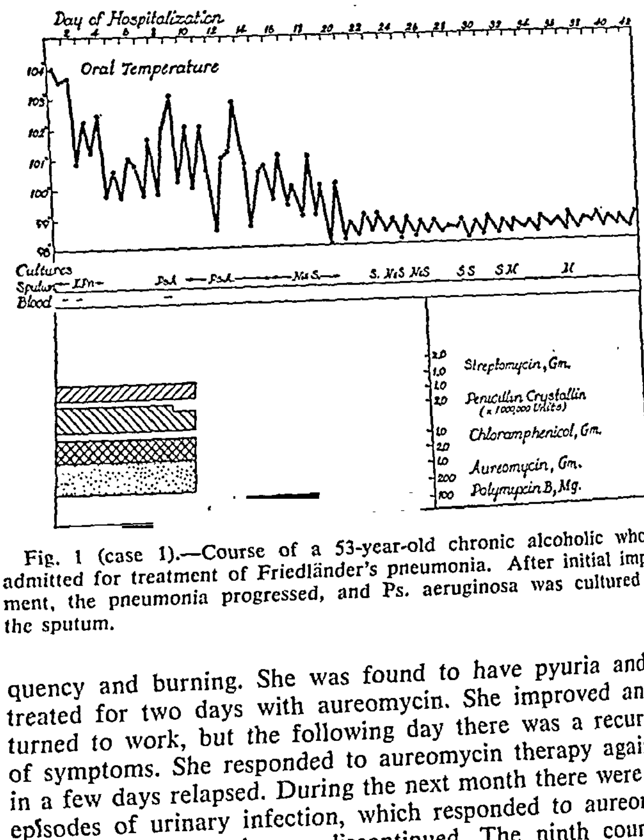

Fig. 1 (case 1).—Course of a 53-year-old chronic alcoholic who was admitted for treatment of Friedländer's pneumonia. After initial improvement, the pneumonia progressed, and Ps. aeruginosa was cultured from the sputum.

Physical examination at this time revealed a chronically and severely ill patient. The liver was slightly enlarged, and there was bilateral costovertebral angle tenderness. Laboratory examinations revealed a moderate leukocytosis and a slight hypochromic anemia. The urine contained albumin (2+), sugar (4+), many white blood cells, and gram-negative bacilli. The blood urea nitrogen level was 107 mg. per 100 cc. Ps. aeruginosa was repeatedly isolated from the urine and blood. The patient was given sulfonamides, methenamine mandelate (mandelamine®), streptomycin, and chloramphenicol without improvement (fig. 2).

Beginning the first of July the patient received polymyxin B intramuscularly in doses of 50 mg. every four hours for 24 hours, followed by 25 mg. every four hours. The blood culture

[2] Deleted on proof.

on the first day after beginning polymyxin B injections was negative and a decrease in the number of bacteria in the urine was recorded; however, cultures of the urine remained positive. Administration of polymyxin B was continued for 10 days, during which the patient's temperature returned to normal and she improved generally. She complained of numbness and tingling of her hands and face and pain at the site of the injections. These symptoms disappeared after discontinuing the drug. At the beginning of polymyxin therapy the urine contained albumin (3+). The amount of albumin in the urine decreased during treatment. At the termination of polymyxin B therapy the urine was not entirely free of pus cells, and the cultures were not sterile. On the second day after discontinuing the drug the fever returned and the abnormalities in the urine progressed. The patient was subsequently explored surgically, and multiple kidney abscesses were found and aspirated. She was then given terramycin with gradual but complete recovery.

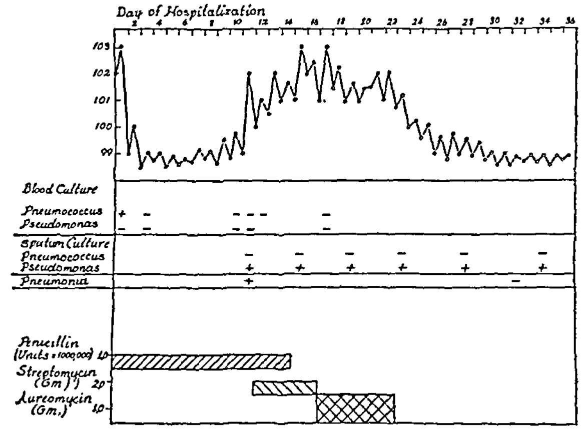

Fig. 4 (case 4).—Course of a 27-year-old woman with Pseudomonas pneumonia following pneumococcal bacteremia.

Case 3.—A 78-year-old man when first seen was comatose. An acquaintance stated that he had apparently been well until about a month previously, when urinary frequency had developed. He was given antibiotics with initial improvement, but while he was still receiving these drugs chills and fever developed. About a week before admission a productive cough developed. Examination revealed an emaciated and chronically ill man with a fever of 103 F, pulse rate of 128, and respiratory rate of 24. There were rales in both lung bases, but the remainder of the physical examination was noncontributory. The white cell count was 4,300, with 50% polymorphonuclear leukocytes; urinalysis revealed a slight trace of albumin, with 5 to 8 white blood cells per high power field. The blood urea nitrogen level was 51 mg. per 100 cc. Administration of penicillin was begun shortly after admission without improvement (fig. 3). He was subsequently given aureomycin and later streptomycin. Proteus vulgaris was isolated repeatedly from the blood and urine. This organism was found to be inhibited in vitro by 31.2 μg of chloramphenicol per milliliter, but resistant to other antibiotics tested. He was subsequently given 0.5 gram of chloramphenicol in acetyl dimethylamine, intramuscularly, every four hours. Blood levels varying between 20 and 50 μg. per milliliter were reached with temporary improvement in the patient's condition. While he was taking the drug, however, the bacteremia returned and he died on the 13th hospital day.

Case 4.—A 27-year-old Negro woman who was a chronic alcoholic was admitted to the hospital because of chills and fever. Physical examination was noncontributory. Her temperature was 103 F. The white blood count was 12,800, with 84% polymorphonuclear leukocytes. Pneumococci were isolated from the blood stream. The patient was treated with penicillin, with a prompt control of the fever and bacteremia (fig. 4). On the ninth day of penicillin therapy the fever returned, and there was clinical and x-ray evidence of pneumonia of the base of the right lung. Beginning with the 11th hospital day, the predominant organism repeatedly isolated from the sputum was Ps. aeruginosa. The penicillin was discontinued, and streptomycin and aureomycin were substituted. There was no definite evidence of the beneficial effect of antibiotic therapy. The patient improved gradually and was afebrile by the 30th hospital day. There was slight residual evidence of pneumonia at discharge.

Case 5.—A 61-year-old salesman had been found to have an adenocarcinoma of the lung and was admitted to the hospital for pneumonectomy. Prior to and following the operation, the patient was given penicillin (fig. 5). Following the operation he developed a bronchopleural fistula and empyema. Cultures of the empyema fluid contained a mixed flora, including Streptococcus hemolyticus, Micrococcus pyogenes, and species of Hemophilus and Neisseria. There was a gradual rise in temperature in spite of the administration of penicillin. On the 10th postoperative day administration of streptomycin was begun and two days later aureomycin was added. There was a prompt improvement. The fever returned, however, and Ps. aeruginosa was isolated from the pleural fluid. The previous therapy was discontinued, and on the 20th postoperative day polymyxin B was given intramuscularly (50 mg. every six hours) and intrapleurally (25 mg. daily). The patient improved slightly, but he continued to have a low grade fever and the chest continued to drain. The number of Pseudomonas colonies cultured from the chest fluid decreased with polymyxin B therapy, but the organism was not entirely eliminated. During the second week of therapy the cultures of the chest fluid revealed staphylococci and hemolytic streptococci. The patient's condition gradually deteriorated, and he died on the 47th hospital day. During the administration of polymyxin B there was no evidence of nephrotoxicity except for occasional mild albuminuria. There was, however, a terminal rise in the blood urea nitrogen to 76 mg. per 100 cc., which was considered to be prerenal and not related to the drug therapy. An autopsy was not performed.

Case 6.—An 18-year-old youth was admitted to the hospital because of hydrocephalus that had developed following a skull injury four years previously. A diagnostic pneumoencephalogram was complicated by purulent meningitis. This infection responded promptly to sulfadiazine, penicillin, and streptomycin. An operation was subsequently performed, anastomosing the subarachnoid space with the left ureter. In spite of prophylactic administration of penicillin and sulfisoxazole (gantrisin®), a spiking fever and purulent spinal fluid developed three days following the operation (fig. 6). Cultures of the spinal fluid revealed P. vulgaris; Esch. coli, P. vulgaris and Pseudomonas aeruginosa were isolated from the urine. The doses of the penicillin and sulfisoxazole were increased, and, when there was no improvement, streptomycin and chloramphenicol were added. There was no response to either of the antibiotics, and on the 23rd postoperative day polymyxin B was given intramuscularly (50 mg. every six hours) and intrathecally (2 mg. daily). The patient improved promptly and on the fourth day th
intrathecal administration of polymyxin B
The intramuscular dose of polymyxin B was

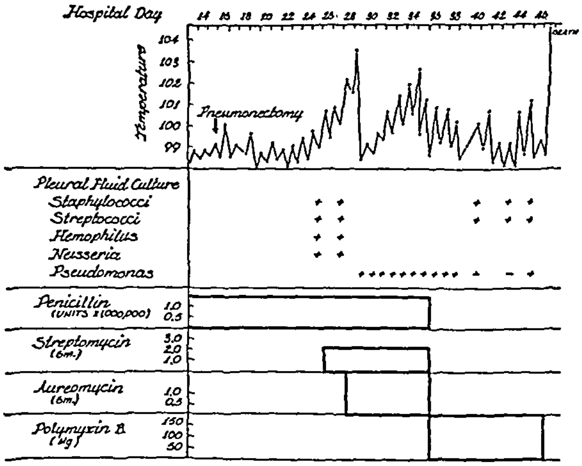

Fig. 5 (case 5).—Course of a 61-year-old man with postoperative empyema.

days of therapy. The patient made an uneventful recovery. During the polymyxin B therapy the patient had no complaints, and results of daily urinalyses were normal except for slight albuminuria and pyuria that had been present prior to therapy. At the beginning of polymyxin therapy the blood urea nitrogen level was 23 mg. per 100 cc., but during therapy it returned to normal. This patient was discharged on the 60th postoperative day without evidence of recurrence of infection.

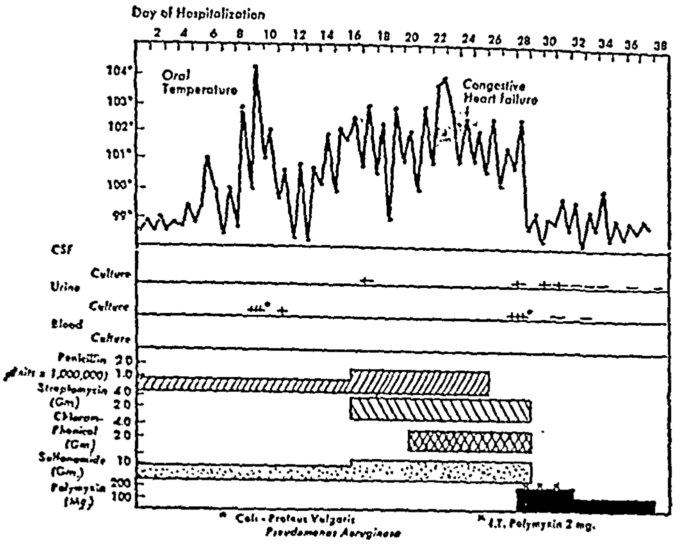

Fig. 6 (case 6).—Course of an 18-year-old youth with postoperative meningitis due to P. vulgaris.

Case 7.—A 54-year-old Mexican was admitted to the hospital because of acute urinary retention. He had been in the hospital previously for an abdominoperineal resection for adenocarcinoma of the colon. At this time he was given prophylactic phthalylsulfathiazole (sulfathalidine®), penicillin, and streptomycin before and following the operation. On admission he had a low grade fever and was given penicillin and streptomycin (fig. 7). In spite of this treatment the temperature rapidly rose to 105 F by the sixth hospital day. Urine cultures revealed a mixed infection, including Aerobacter aerogenes, Esch. coli, Streptococcus hemolyticus, P. vulgaris and Ps. aeruginosa. Blood cultures were sterile. Penicillin and streptomycin were continued and on the eighth hospital day, terramycin was added to the regime. There was rapid clinical improvement, and a transurethral resection was performed on the 22nd hospital day. The following day there was a sharp rise in temperature and P. vulgaris was isolated from the blood stream. In addition to continuing administration of penicillin and streptomycin, administration of terramycin was again begun on the 23rd hospital day. There was no clinical improvement, and blood cultures were consistently positive for Proteus vulgaris. The penicillin dosage was increased and sulfithoxazole was added. On the 28th day the patient developed cutaneous petechiae and had two subsequent pulmonary infarctions. In vitro sensitivity tests indicated that this strain of Proteus was resistant to penicillin, streptomycin, and terramycin, but relatively sensitive to chloramphenicol (inhibited by 31.2 µg per milliliter). He was consequently given chloramphenicol but had congestive heart failure and died two days later. Autopsy revealed bilateral pyelonephritis, generalized carcinomatosis, and pulmonary congestion and infarctions.

Case 8.—A 61-year-old publisher was admitted to the hospital with chills and fever, urinary frequency, and burning. He had had previous episodes of acute urinary infections that had responded to either sulfonamides, penicillin, streptomycin, or aureomycin. In addition, he had arteriosclerotic heart disease with a recent myocardial infarction and congestive heart failure. Urinalysis on admission revealed albumin (4+), many white blood cells, and occasional red blood cells. The white blood cell count was 26,000 per cubic millimeter. The blood urea nitrogen level was 12 mg. per 100 cc. Ps. aeruginosa was cultured from the urine and blood. He was treated with sulfithoxazole and aureomycin without improvement (fig. 8). On the fourth hospital day intramuscular injections of polymyxin B were begun (50 mg. every six hours). Ps. aeruginosa was not cultured from the urine after the fifth hospital day, and blood cultures became negative. On the fourth day of therapy the temperature had returned to normal, and the dose was reduced to 25 mg. every six hours. The following day a transurethral prostatic resection was performed. Administration of polymyxin B was continued for a total of 11 days, during which time the pyuria disappeared, the albuminuria varied from 1+ to 4+, and the urinary output and blood urea nitrogen remained within normal limits. No evidence of recurrent infection occurred during this hospitalization. The patient was discharged on the 18th hospital day.

COMMENT

The patients discussed illustrate what is believed to be an increase in relative importance of Proteus and Pseudomonas in the production of infectious processes that may arise during antibiotic treatment of other infectious diseases. Clinical experience suggests that there might also be an actual increase in frequency of infections due to these organisms since the introduction of the agents with the broadest antimicrobial spectra. In an analysis (fig. 9) of the routine cultures received in the bacteriology laboratory of a large general hospital, the incidence of Proteus in the specimens received rose from 8% of the gram-negative bacilli recovered in June, 1948, to 32% in January, 1951. During the same time the incidence of Pseudomonas recovered increased from 15% to 30%. These data also reflected the clinical experience reported by others of the increase in the frequency of infections due to Candida (Monilia).[3] During the same period of two and one-half years there was a relative decrease in the isolation of certain other gram-negative bacilli, particularly Esch. coli. One cannot conclude from these figures that there has been an actual increase in clinical infections due to Proteus and Pseudomonas, since they are based on laboratory reports and not individual patients. The results of this study indicate, however, that these organisms are oftener present in body fluids or exudates and may serve as potential sources of infections.

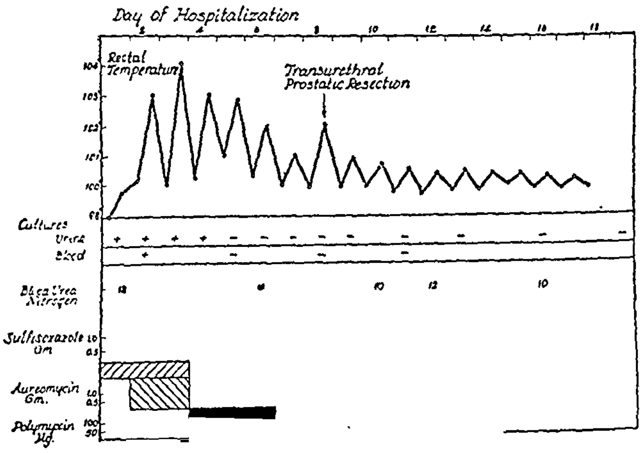

Fig. 8 (case 8).—Course of a 61-year-old man with an acute urinary infection previously treated with antibiotics. Ps. aeruginosa was cultured from the urine.

The isolation of Proteus or Pseudomonas from a patient does not necessarily mean that either of these organisms is playing a significant role in the production of an infectious process, since they are both normal inhabitants of the skin and the mucous membranes of the respiratory and gastrointestinal tracts. If the organisms are isolated in pure culture repeatedly from body fluids that are normally sterile, such as the blood stream, spinal fluid, or urine, in the presence of clinical evidence of infection, there can be little doubt as to their significance. When they are obtained in mixed infections or from skin secretions or mucous membrane surfaces, it may be difficult to evaluate their importance. However, if there is clinical and laboratory evidence of progressive infection and either of these two organisms is isolated in pure culture or as a predominant organism the importance of their role in pathogenesis must be strongly considered and their control undertaken.

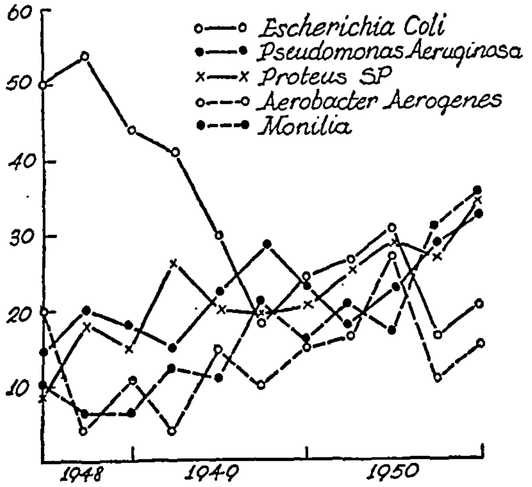

Fig. 9.—Analysis of results of routine cultures in a large general hospital illustrating the relative frequency of some of the gram-negative bacilli.

The relationship of the infections to the antimicrobial therapy was thought in most patients to be simply a matter of the elimination of sensitive species of bacteria, permitting the multiplication of resistant species. Since Proteus and Pseudomonas are usually the only bacteria surviving the action of the most recently introduced antibiotics, they are frequently the only remaining etiological possibilities. There was, moreover, a disturbance of some fundamental defense mechanism against infection in many of the patients. In some of the patients the infections resulted from anatomical defects prevented the adequate drainage of contaminated material. Urinary infections associated with prostatic or ureteral obstructions were frequently observed. Bronchiectasis and undrained abscesses are other examples. In other patients infected material was introduced into a closed body space, such as by puncture wounds of the bowel or chest either from trauma or operation, or by the contamination of the cerebrospinal fluid.

The onset of the signs and symptoms of the Proteus and Pseudomonas infections frequently occurred after a period of improvement following suppression of the initial etiological agent. This is illustrated by the patient (case 1) with cirrhosis of the liver in whom a Friedländer's pneumonia developed. This improved with the institution of massive antibiotic therapy, but later the pneumonia spread in spite of continued therapy. In case 4 pneumonia developed due to Pseudomonas while the patient was still receiving penicillin that had controlled pneumococcal bacteremia.

The course of the Proteus or Pseudomonas infections was quite variable. The correction of the underlying anatomical defect and surgical drainage was frequently adequate to control the infection. Other patients were able to develop sufficient immunity to overcome the infection when the antibiotic therapy was discontinued and the normal bacterial flora reestablished. The administration of specific antibacterial agents sometimes played a significant role in shortening the course of the infection. In four patients no therapy was effective and the infection contributed to a fatal outcome.

An important factor in controlling the infections studied was establishment of adequate surgical drainage and removal of nonvital tissue. In urinary tract infections, particularly, antibiotic therapy usually produced only transient benefit if adequate urinary drainage was not achieved. The extent of the surgery necessary varied considerably. Needle aspiration was sufficient drainage in a patient with septic arthritis. In postoperative empyema extensive surgical drainage in conjunction with streptokinase and streptodornase administration was necessary in some cases.

When a particular strain of Proteus or Pseudomonas was found to be sensitive in vitro to one of the antibiotics, the administration of this agent was found to play a valuable part of the management of the infection. Because of the wide variation in sensitivity of Proteus and Pseudomonas to antibiotics, in vitro sensitivity tests were routinely performed as an aid in selecting the agent of choice. The results of such in vitro tests using the tube dilution method against 50 strains of Pseudomonas are illustrated graphically in figure 10. These findings illustrate generally the resistance of Pseudomonas to most of the antibiotics as contrasted to the high degree of sensitivity to polymyxin B. The chart does not, however, present an entirely accurate picture, since some of the strains tested were isolated from patients who had already received one or more of the antibiotics, thus eliminating some of the more sensitive strains from the survey. Furthermore, the arbitrary test level of 15.6 μg per milliliter indicating sensitivity in this table may not entirely parallel the results in patients, since this drug level may not be attained in the infected tissues and body fluids. The study indicates, however, that the largest number of strains of Pseudomonas were sensitive in vitro to polymyxin B. Many were also sensitive to terramycin and neomycin.

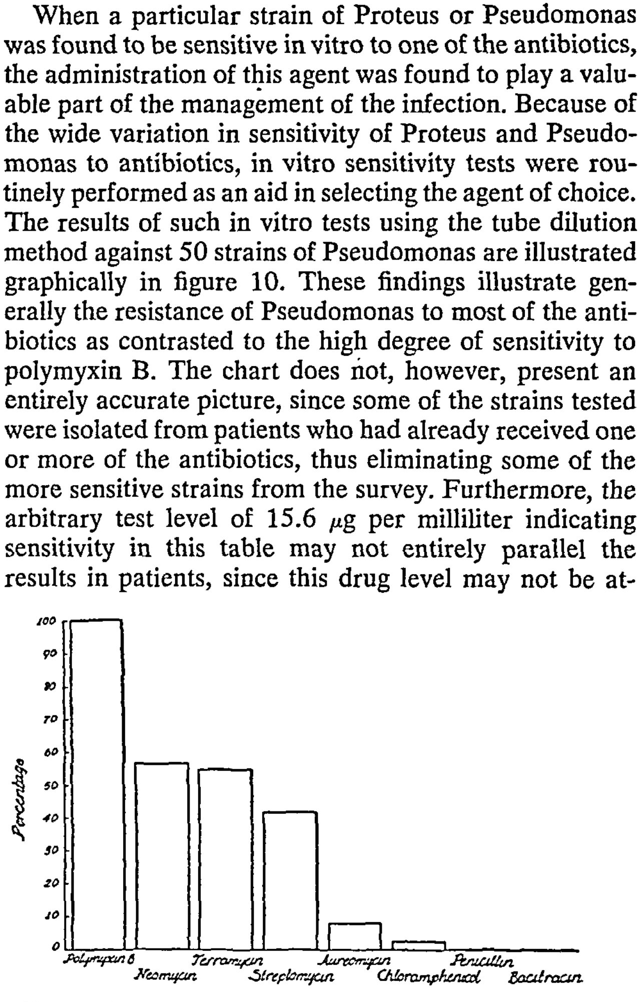

Fig. 10.—The in vitro sensitivity of 50 strains of Pseudomonas to various antibiotics at a concentration of 15.6 μg per milliliter.

A similar study was performed using 20 strains of Proteus. Many of these organisms were partially inhibited by the antibiotics against which they were tested, but only an occasional strain was completely inhibited by concentrations of the drugs obtained in the body fluids by the usual dosage schedules.

A summary of the results of the antibiotic therapy in the 56 cases reported in this series reveals that polymyxin B was the most effective agent in the treatment of Pseudomonas infections. In the nine patients in whom it was used, the infections were satisfactorily controlled in seven, or 78%. In contrast to reports following the use of less pure preparations, there was no evidence of significant toxicity noted from the use of this antibiotic. Terramycin and streptomycin exerted a favorable influence on the course of the infection in an occasional patient. Neomycin was not evaluated clinically because of other reports of toxicity following parenteral administration. Antibiotics played a less significant role in the treatment of the Proteus infections. Two patients with polymyxin-sensitive strains responded to the use of this drug. Streptomycin, given with large doses of one of the sulfonamides, is probably still the best treatment for infections due to this organism.

Number of Patients in Whom Pseudomonas or Proteus Infection Developed During or Following Antibiotic Therapy

Infection	No. of Cases	
	Pseudomonas	Proteus
Bacteremia	4	2
Pulmonary infections	5	0
Empyema	4	0
Meningitis	3	1
Peritonitis	0	1
Arthritis	1	0
Urinary infections	19	15
Prostatitis	1	0

SUMMARY

The suppression of the other bacteria by the widespread use of antimicrobial agents has increased the relative importance of Proteus and Pseudomonas as causative agents in infectious processes. Cases of infections due to these organisms that developed during or following repeated courses of antibiotic therapy are reported. The relationship of the infection to the antibiotic therapy was believed in most patients to be a matter of change in bacterial flora owing to elimination of sensitive bacteria and multiplication of resistant species. The importance of being aware of the possibility of Proteus or Pseudomonas infections in patients who originally respond to antibiotic therapy but who present evidence of renewed infection while still receiving therapy is illustrated by the patients described. The possible seriousness of giving the broad spectrum antibiotics prophylactically must be considered; since if an infection does occur with a nonsensitive organism during such therapy, it is almost certain to constitute a difficult therapeutic problem.

The problem of treatment of Proteus and Pseudomonas infections is considered. Streptomycin in combination with large doses of sulfonamides was the most effective therapy in Proteus infections. Polymyxin B was most consistently effective in Pseudomonas infections, though some strains were sensitive in vitro to terramycin. The correction of any underlying anatomical disorder was considered a most important part of management. The discontinuance of ineffective antibiotics was sufficient in some patients to control the infection by allowing the reestablishment of normal bacterial flora.

THERAPEUTIC VALUE OF PROBENECID (BENEMID®) IN GOUT

Luke R. Pascale, M.D., Alvin Dubin, M.S.
and
William S. Hoffman, M.D., Chicago

Probenecid (benemid®) was first introduced into clinical medicine by Boger[1] as an adjunct to penicillin and paraaminosalicylic acid therapy. Probenecid has been found to be a powerful agent that reversibly inhibits renal tubular transfer, suppressing tubular secretion of penicillin, paraaminosalicylic acid, paraaminohippuric acid, and phenolsulfonphthalein.[2] In this respect it is similar to carinamide; but while the latter is required in doses of 18 to 24 gm. per day for its tubular effect, probenecid accomplishes the same results in doses of 2 gm. daily. That probenecid, like carinamide, is also capable of blocking tubular reabsorption of glomerular constituents was demonstrated by Schneider and Corcoran,[3] who were able to increase the excretion of phosphate by administration of the drug. Gutman, acting on the report by Wolfson and associates[4] that carinamide was a uricosuric agent, demonstrated that probenecid had a similar effect, presumably by blocking the partial reabsorption of filtered urate. A preliminary report by Gutman on the efficacy of probenecid in the treatment of gout has recently appeared.[5] Bishop and associates[6] also reported a uricosuric activity of probenecid but with no clinical studies.

The similarity of action of probenecid to that of carinamide led us independently to study the potential value of this new drug in the treatment of gout. Our studies were begun without benefit of the experiences of Gutman and Bishop. In these studies, after a preliminary demonstration of the uricosuric action of probenecid, an effort was made to determine an adequate dose schedule in the treatment of gout, the extent of improvement in patients with gouty arthritis, and the possible toxicity from prolonged administration.[7]

Mrs. Anne Whittier made the chemical analyses for this study.

Presented in part before the Central Society for Clinical Research, Chicago, Nov. 2, 1951.

From the Hektoen Institute for Medical Research of the Cook County Hospital, the Department of Medicine, Stritch School of Medicine, Loyola University (Dr. Pascale), and the Department of Physiology, University of Illinois College of Medicine (Dr. Hoffman).

Med. 33:18-31 (July) 1950. Boger, W. P.; Pitts, F. W., and Gallagher, M. E.: Benemid and Carinamide: Comparison of Effect on Para-Aminosalicylic Acid (PAS) Plasma Concentration, J. Lab. & Clin. Med. 36:276-282 (Aug.) 1950.

METHODS AND MATERIALS

The 20 male subjects for this study were ambulant or bed patients of the Cook County Hospital. The diagnosis of gout was established in all these patients by the history or observation of typical acute gouty attacks and by the finding of elevated serum uric acid concentration. In seven patients there was the additional evidence of tophi and/or diagnostic x-ray changes. Limitation of joint motion was seen in these seven as well as in four other subjects. In four subjects the limitation was severe, in five it was moderate, and in the remaining two it was mild. Ten of the patients were under observation for periods of five to seven and a half months. Six more were followed for two to five months. Four patients were dropped from the study after the preliminary survey.

The demonstration of the uricosuric effect of probenecid therapy was carried out in the first five patients studied. The subjects were placed on a standard low purine diet. After a control period, probenecid was prescribed in doses of 0.5 gm. (one tablet) every six hours. The 24-hour urine collection and the serum were analyzed for uric acid by a photoelectric modification [8] of the Folin method. (Since the values were comparative, no effort was made to eliminate the nonspecific chromogen by the use of uricase. Wolfson and associates [9] have shown that true urate of serum and urine in gouty patients consistently represents 85% to 90% of the apparent urate. The range of serum concentrations in normal persons by this method was 3.0 to 5.9 mg. per 100 cc.) With increased excretion of urate and a fall in the serum urate level, probenecid therapy was discontinued to allow a return to pretreatment conditions. Then the experiment was repeated.

Several regimens were tried out in most of the patients. These included administration of 2 gm. of probenecid daily, 2 gm. every other day, and 2 gm. for only two successive days out of each week. In three patients the effect of acetylsalicylic acid simultaneously administered with probenecid for four days was compared with that of probenecid therapy alone. During the later part of the study five patients were not given probenecid and treated with 5.2 gm. of acetylsalicylic acid and 8 gm. of sodium bicarbonate daily for three weeks. The administration of 2 gm. of probenecid daily was then resumed.

A standard low purine diet was used only for the patients hospitalized for the urine studies, chiefly to assure a constant purine intake. During the period of the various maintenance regimens, the patients were allowed a more or less general diet.

The possible toxicity of probenecid was studied by weekly physical examinations and frequent blood chemical analyses. The latter included the determination of nonprotein nitrogen, albumin, globulin, calcium, phosphorus, alkaline phosphatase, chloride, sodium, potassium, carbon dioxide capacity, cholesterol, cephalin cholesterol flocculation, and thymol turbidity. Also, at frequent intervals complete blood cell counts were made and routine urine examinations performed.

* Based on 24 hour output.

† Uric acid clearances were determined on the third or fourth day, after stabilization of serum uric acid levels had occurred.

RESULTS

Effect of Probenecid on Urinary Urate Excretion and on Serum Urate Level.—An increase in urinary excretion of urate occurred promptly in 17 of the 20 patients studied. In the five subjects of whom protracted quantitative studies were made, the increase was equivalent to 35% to 200% of the control excretion. In some instances the 24-hour urine contained 1.5 to 2.4 gm. of urate. Much of it was already precipitated in the collection bottle. The initial high excretion was not maintained. Gradually it fell, corresponding to the lowering of the serum uric acid concentration (fig. 1). The pattern of excretion was similar to that reported by Gutman [5] and by Bishop and associates.[6] The roughly estimated 24-hour urate clearances were increased two to fourfold by the administration of probenecid (see accompanying table). This increased clearance was still effective during the diminished excretion, the latter merely reflecting the fall in serum uric acid concentration. Though continuous quantitative collections of the urine were carried out only in the first phase of the study, occasional 24-hour analyses gave us the impression that the daily excretion of urate during administration of probenecid was always higher than that of the control period, at least in the patients with tophaceous gout, just as was found by Gutman.

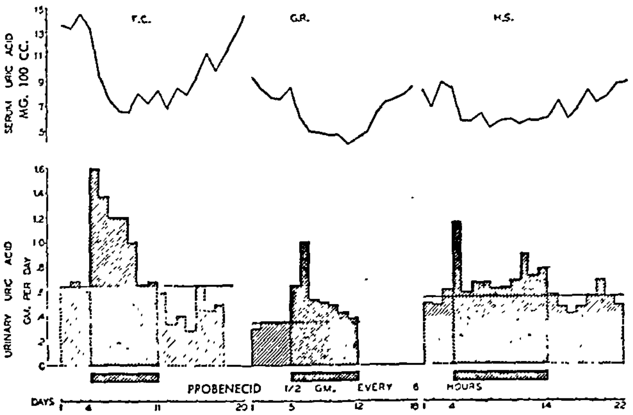

Fig. 1.—Effect of probenecid on urinary uric acid excretion and serum uric acid levels.

A prompt precipitous fall in the serum urate concentration occurred in 14 subjects, as illustrated in the cases shown in figure 1. Three patients showed a more gradual fall in serum levels, the nadir not being reached until 96 or 120 hours. In three other subjects no decrease in the serum uric acid level occurred, even though 2 gm. of probenecid was administered daily for one to three weeks. The failure was apparently associated with the renal

insufficiency discovered in these subjects. Two had urea clearances of 26% and 27% of normal, respectively, and the third had chronic azotemia with nonprotein nitrogen levels ranging from 68 to 85 mg. per 100 cc. These three unresponsive patients were not studied beyond the three-week period.

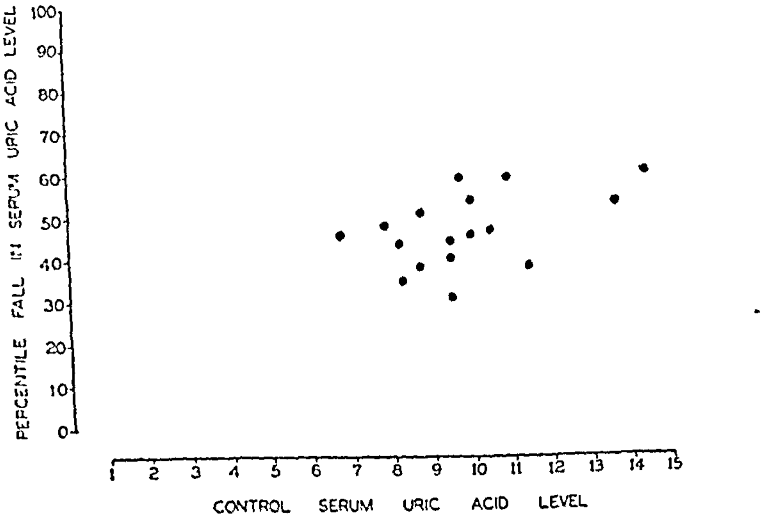

Fig. 2.—Relation of percentile fall in serum uric acid levels after 72 hours of probenecid therapy to the control (pretreatment) serum uric acid levels, in milligrams per 100 cc.

The percentile fall in the serum urate level at the end of the 72 hours in the 17 subjects who responded to probenecid therapy ranged from 30% to 58%, the average fall being 45%. In some instances a lower serum level was encountered several days later, but for the most part the serum concentration rose slightly with continued probenecid therapy and was maintained at a level slightly higher than that of the nadir. There was no significant correlation between the percentile fall and the height of the control serum urate concentration (fig. 2).

In the five patients who were given 2 gm. of probenecid daily for only the first two days of each week, the initially lowered serum uric acid level was not maintained; instead, there was a rapid rise during the next five days to the pretreatment levels. With each new two-day period of probenecid administration, the serum uric acid level fell as promptly as before. Though in several instances the extent of the fall with each new treatment period appeared to be slightly less than previously, there were no instances of developed refractoriness to probenecid therapy. Figure 3 is illustrative of the curves obtained.

During the course of the study 16 subjects were maintained on a regimen of 2 gm. of probenecid given every other day for periods ranging between 4 and 15 weeks. The response to this dosage varied unpredictably. Four patients, within the first two weeks, had a slow but steady rise in serum uric acid concentration above the initially obtained minimal level. In four more, a rise eventually occurred but was delayed for 6 to 10 weeks. In the remaining eight patients, though an initial rise might temporarily have occurred, the depressed serum uric acid level was on the whole well maintained during the 4 to 15 weeks of observation. However, all the patients who were again given 2 gm. of probenecid daily showed a further depression of the serum uric acid concentrations. There was no doubt that, insofar as serum levels were concerned, the most satisfactory regimen was a dosage of 2 gm. of probenecid daily given continuously. For greater convenience the medication schedule was 1 gm. given twice a day instead of 0.5 gm. given every six hours, without any appreciable change in the serum levels. With this continuous therapy the uric acid concentration could be maintained indefinitely at levels ranging from 4 to 8 mg. per 100 cc., with occassional temporary rises, especially at times of an acute attack.

One of the 20 patients in this study died suddenly of coronary occlusion after preliminary daily treatment with probenecid for four weeks. He was 76 years old. Autopsy revealed no anatomic defects that could be related to the administration of probenecid.

Effect of Probenecid on the Symptoms of Gout.—In figure 4 are summarized the pertinent clinical data of the 16 patients who were treated with probenecid for an extended period. The eight patients who displayed limitation of joint motion all showed progressive improvement during probenecid therapy. G. R., a barber with gout for five years, had not been able to work more than three days a week, if at all, during the past three years because of stiffness and pain in the joints of the extremities. After six weeks of probenecid therapy he became completely relieved of pain and joint dysfunction and is now working at his trade six full days per week, with continued medication. O. B. had been completely bedridden for a period of one year because of gouty arthritis. This lesion was superimposed on a residual paralysis of the right lower extremity and weakness of the left foot resulting from poliomyelitis. After five months of probenecid therapy, he was able to walk with the aid of his brace and crutches as well as he did before the onset of gout. J. B. had been bedridden two months with continued pain and severe limitation of joint movement. At the end of three months of probenecid therapy he was able to walk unaided and to drive his automobile. Five other patients showed comparable, if less dramatic, improvement. Of this group, H. P. and P. K., both of whom had large tophaceous deposits in the hands, showed the least benefit from treatment, but even in these two there was enough improvement, both objective and subjective, to make them enthusiastic over the treatment and desirous of its continuation.

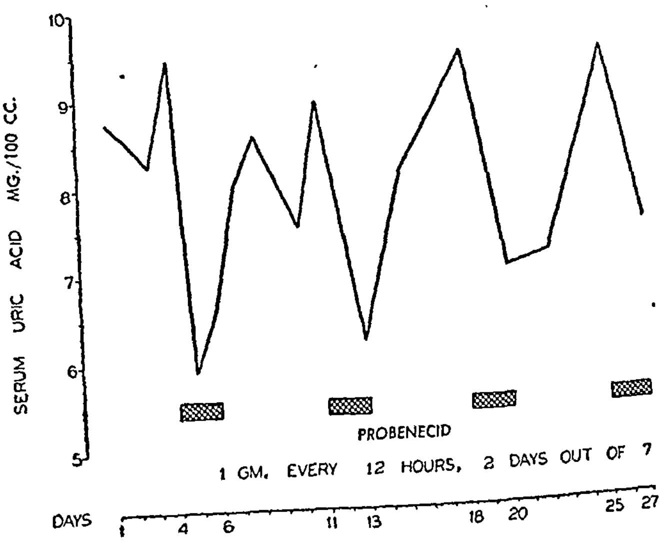

Fig. 3.—Serum uric acid levels in patient receiving intermittent probenecid therapy.

In the eight patients with acute recurrent gout without symptoms in the intercritical periods, the results of therapy were, of course, more difficult to evaluate. The serum uric acid was maintained in these persons at levels only slightly higher than the upper limits of normal without any restrictions of diet. This was an important benefit in itself. The patients felt well and had no complaints, but patients with recurrent gouty attacks usually acted that way even without medication. Three of these patients had acute attacks during the period of medication. J. D. had a moderately severe attack after six days of probenecid therapy, which lasted four days; then he had a mild attack four weeks later, which lasted two days. P. M. had one attack during the three and a half months of therapy, and F. M. had one mild attack after three months of therapy. The remaining five patients were free of acute manifestations of gout during the therapeutic study; but, since they normally had only two or three attacks a year, a much more prolonged study will be required to ascertain the effect of probenecid therapy on the incidence of acute joint manifestations.

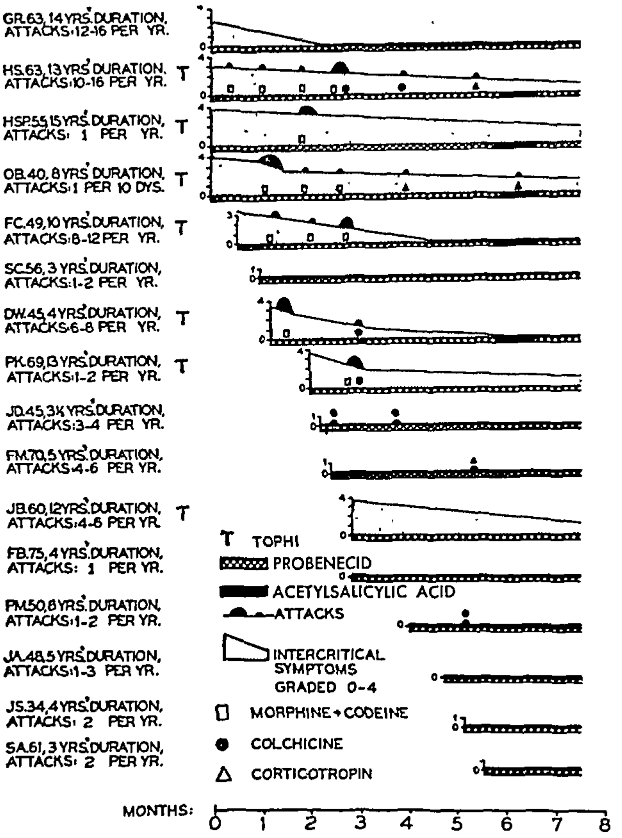

Fig. 4.—Clinical course of 16 patients with gout during probenecid therapy.

The fact that one or more attacks occurred in nine patients during probenecid therapy is an important physiological as well as therapeutic problem. Gutman [5] has reported the same phenomenon, and he has attributed the attacks to the action of probenecid. This may be the case, but it is far from certain. The attacks occurred principally in those patients who had had them frequently before probenecid therapy and who had chronic gouty arthritis with multiple urate deposits. In the first attacks we were courageous enough to continue probenecid therapy and to avoid the use of colchicine or corticotropin (ACTH). Only codeine or morphine were utilized for the pain. As a consequence, the attacks were rather prolonged, some lasting 12 days. It was obvious that probenecid had no colchicine type of action. It neither relieved the acute pain nor shortened the length of the attack. With the subsidence of the inflammation in the acutely involved joint, there was usually less limitation of motion in that joint than before the attack. D. W., for example, before the first attack in his left knee during probenecid therapy, had had only 80 degree flexion of the knee joint. After the attack subsided, he was able to bend the knee 135 degrees, or practically normally. Succeeding attacks in the same patient usually migrated to other joints.

The frequency and intensity of acute attacks in the patients with chronic gouty arthritis appeared to diminish with continued probenecid therapy, as is seen in figure 4. When it was finally recognized that probenecid therapy was of no value for the acute attacks, subsequent episodes were managed with colchicine or corticotropin [10] therapy. The former was given in doses of 0.65 mg. (1/100 grain) every four hours until diarrhea set in. Corticotropin was used in four attacks in doses of 10 mg. every six hours; two to four injections were required. Whether colchicine or corticotropin was used, the attacks usually subsided completely in 24 to 72 hours.

Effect of Salicylate on the Uricosuric Action of Probenecid.—It is well known that sodium salicylate or acetylsalicylic acid given in large doses has a uricosuric effect and that with prolonged administration a lowering of the serum urate level is produced in gouty subjects. It was interesting, therefore, to determine the influence of acetylsalicylic acid administered simultaneously with probenecid. To our surprise, acetylsalicylic acid given in doses of 1.3 gm. every six hours completely suppressed the effect of probenecid. The blood urate remained at least as high as without any medication. When acetylsalicylic acid therapy was stopped after four days, while probenecid therapy was continued, the fall of the serum uric acid was just as prompt and as precipitous as in

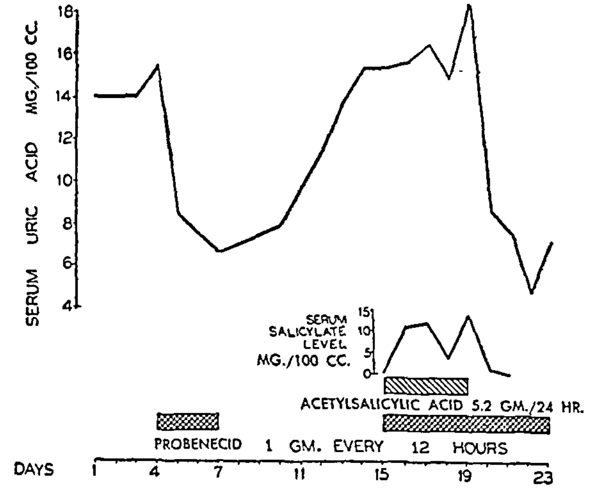

Fig. 5.—The influence of acetylsalicylic acid therapy on the ability of probenecid therapy to lower the serum uric acid concentration.

---

[10] The corticotropin used was furnished by the Wilson Laboratories, Chicago.

previous probenecid therapy. Identical results were seen in the three patients in whom this effect was studied. One experiment is shown in figure 5.

The fixation of the serum uric acid level when acetylsalicylic acid was given along with probenecid was almost certainly due to a blocking of the uricosuric action of probenecid. It could not be due to falsely high serum uric acid levels, because of the presence of salicylates or its metabolites in the blood. We have made innumerable determinations of uric acid in gouty and nongouty patients during salicylate therapy and have never found any false elevation of serum uric acid. However, to prove conclusively that salicylates exert their influence by preventing the uricosuric effect of probenecid and to determine at what threshold serum salicylate level this inhibition occurs, it is necessary to carry out urine urate analyses. One must take special precautions in analyzing urine for urate during salicylate therapy, for it has been shown [11] that gentisic acid, a metabolite of salicylate, may on occasion raise the apparent urine urate concentration by as much as 25% even when the uricase method of analysis is utilized. Such studies are now in progress.

Some of the five patients were maintained for a period of three weeks on a regimen of 1.3 gm. of acetylsalicylic acid and 2 gm. of sodium bicarbonate given four times a day for five out of each seven days. The serum uric acid concentration rose in all these patients from the low level of the previous probenecid regimen to the high control levels. Slowly the concentration diminished in two of these patients, but it never fell to the level found in the probenecid therapy period.

Toxic Effects of Probenecid Therapy.—On the whole the patients remained remarkably free of side-effects of probenecid therapy. Only three patients had changes that could be attributed to toxicity due to probeneicd. H. S. had a rash, which disappeared without recurrence in spite of continued probenecid therapy. During his only gouty attack while receiving treatment, proxysmal auricular fibrillation developed. This arrhythmia was converted to normal by digitalization. The rhythm has since then remained of sinus origin. J. A. had epigastric distress, which subsided after two days despite continued therapy.

The one potentially serious complication occurred in O. B. This was the development of urate crystalluria and hematuria early in the course of treatment with probenecid. Treatment with the drug was temporarily stopped, and the complications disappeared within two days. After eight days, probenecid therapy was resumed and was supplemented with administration of sodium bicarbonate and an increased water intake. There was no recurrence of the urinary findings.

Blood chemical analyses showed no significant deviations from normal that might indicate renal or hepatic injury or disturbances of electrolyte metabolism. Serum phosphate levels were at low normal. Since the data of the chemical analyses were not enlightening, they have been omitted. Complete blood cell counts made serially gave no evidence of inhibition of normal erythropoiesis and granulopoiesis or of any other abnormality. There were no alterations found in the urine on repeated routine examinations, except for heavy urate precipitations when the specimens were allowed to stand.

COMMENT

Gout is still a mysterious disease, the etiology and pathogenesis of which have not been unraveled; yet modern investigations point to three fundamental features of the gouty patient that must be understood if the potentialities of probenecid therapy are to be appreciated:

1. Gout occurs in patients with familial hyperuricemia.[12] The cause of the elevated serum uric acid level has not been determined, but it may be (*a*) overproduction of uric acid, (*b*) diminished destruction of uric acid, or (*c*) diminished renal excretion of uric acid. In the last analysis, it is absolute or relative renal inefficiency that is responsible for the hyperuricemia, for the normal urate clearance is only 5% to 10% of the glomerular filtration rate, a large portion of the filtered urate being reabsorbed by the tubules by active enzymatic processes.[13] The system of the gouty patient, instead of adjusting excretion by diminishing tubular reabsorption, attempts to do so by raising the level of serum uric acid.

2. Hyperuricemia is attended by actual or potential supersaturation of urate in the interstitial fluids, at least in special sites, such as around joints, in bursae, and in cartilage. Thus hyperuricemia ultimately defeats its own purpose. With precipitation of urates in the tissues, the serum level should fall. However, a renewed high level is soon established to maintain excretion, which level allows further precipitation. Repeated waves of positive balance of uric acid are thereby produced by the very hyperuricemia designed to avoid this eventuality. From the work of Benedict and his associates [14] with isotopic uric acid, it appears that the freshly precipitated urate is in the form of fine crystals that are easily redissolvable and are part of the miscible pool of uric acid. The older deposits, however, particularly the material in the depth of tophi, are chalky and much less soluble. This portion is not in equilibrium with the soluble or dissolved urate.

3. The gouty patient has a unique exaggerated inflammatory reaction to precipitation of urates in the region of the joints, associated with severe pain, swelling, and limitation of motion. This reaction is promptly reversible by the administration of colchicine or corticotropin, without relation to any change in the excretion of urate.[5] The fact that gouty patients even during intercritical periods have low excretions of 17-ketosteroids,[15] the fact that the administration of small quantities of corticotropin is effective in reversing such attacks, and the fact that gouty attacks are induced by all the stresses that are known to call for an increased production of adrenocortical hormones and by administration of corticotropin followed by its withdrawal,[16] all point to a disturbance in adrenal function in gouty patients.

Probenecid therapy attacks the problem of gout at the level of renal excretion. It does nothing for the specific gouty response to urate deposition; it merely removes the hyperuricemia. Probenecid is apparently the most effective and most harmless uricosuric agent so far discovered. It is far more effective than neocinchophen or acetylsalicylic acid, without the attendant dangers of these drugs. It produces a large negative balance of uric acid when first administered at a time of high serum uric acid levels, and a continued small negative balance when the serum level has been lowered to near the upper limit of normal. Gutman has estimated an extra excretion of about 75 gm. in five months. Though we have been unable to carry out prolonged urine collections to determine this excretion, extrapolations from our limited data would tend to confirm Gutman's estimation.

The therapeutic value of the negative uric acid balance produced by probenecid was unequivocal in the patients with chronic tophaceous gout. The disability was diminished in all cases and almost completely removed in several. Apparently the urate that is first removed is in the form of easily soluble crystals loosely deposited around the joints and on the surface of old tophi. Benedict and associates [14] have demonstrated that as much as 29 gm. of such miscible urate deposits can be removed in three months by the uricosuric effect of acetylsalicylic acid. The rate of removal with probenecid therapy is undoubtedly greater.

Benedict and his associates have called attention to the fact that the removal of urate deposits by acetylsalicylic acid in their case was accomplished without a significant lowering of the serum uric acid level. However, it has been our experience both in the several weeks of acetylsalicylic acid therapy in the present series of cases and in long-term studies in other cases that the serum uric acid level does slowly fall with continued acetylsalicylic acid therapy. Nevertheless, it is undoubtedly true that administration of acetylsalicylic acid does not produce the rapid fall in serum level accomplished with probenecid therapy. Apparently the uricosuric effect of probenecid therapy is so great that excretion is always ahead of resorption of deposited uric acid, whereas in the case of acetylsalicylic acid therapy the excretion is slow enough to allow solution to keep pace with it, as long as an appreciable store of easily miscible urate is available. Eventually, as the miscible pool shrinks, the excretion becomes slightly faster than solution, and the serum uric acid level slowly declines.

It was impossible in the short period of the present study to evaluate the effective probenecid therapy on recurrent nontophaceous gout. Nevertheless, it is fair to prophesy that, with continued therapy and with the maintenance of the serum levels near the range of normal, tophi will be prevented from forming and that eventually acute gouty episodes will seldom occur. Of course, such an eventuality will depend on the innocuousness of continued probenecid therapy over a long period.

It is possible, though far from certain, from our data and from those of Gutman that acute attacks are precipitated shortly after the beginning of probenecid therapy, at least in patients with chronic tophaceous gout. The mechanism of this development in the presence of a much lowered serum uric acid level is difficult to visualize. Perhaps solution of urates takes place in one region while reprecipitation takes place in another region, where local factors (which might be characteristic of gout) are conducive to disturbances of the supersaturated solution. At any rate it is our clinical impression that these attacks are not likely to occur in the same joint again with continued probenecid therapy and that the rate and intensity of recurrence ultimately diminishes. Certainly, with the recognized efficiency of colchicine and/or corticotropin therapy in alleviating the acute episodes, this circumstance should prove no contraindication to probenecid therapy.

The blocking effect of acetylsalicylic acid on the uricosuric action of probenecid was unexpected. If salicylates act, as Levine and associates maintain,[17] by freeing serum urate from its combination with serum protein, this annulling effect should not occur, whether probenecid owes its uricosuric effect to a similar liberation of urate from protein or whether it acts by interfering with tubular reabsorption of urate. Indeed, one should expect a synergistic effect. In consideration of the recognized action of probenecid in preventing tubular excretion of penicillin and paraaminosalicylic acid, it appears unreasonable to look elsewhere than in the tubules for the uricosuric effect of probenecid.

Salicylate probably exerts its interference with the action of probenecid directly in the tubules. It has been demonstrated [18] that, unless the urine is strongly alkaline, 50% to 80% of ingested salicylate or acetylsalicylic acid is excreted as salicyluric acid or salicyl glycuronide. Almost all of this conjugation takes place in the renal tubules. If we assume that probenecid produces its blocking action on urate reabsorption only after it is conjugated in the tubular cell, then it is possible to visualize the negating effect of salicylate as being due to its competition with probenecid in the tubule for the conjugating enzymes. This hypothesis is not out of accord with Beyer's theory of tubular transport mechanism.[2]

Obviously we have not been able to explore all possible dosages of probenecid. On the basis of previous experience with probenecid in penicillin and paraaminosalicylic acid therapy, we have kept the daily dosage at 2 gm. per day, but have varied the days of treatment, hoping to find a less rigorous management than daily administration satisfactory. Though we could see no clinical difference between the dosage of 2 gm. of probenecid given every day and that of 2 gm. given every other day, it was clear that in only a few patients—usually those without tophi—could the serum urate level be kept relatively low without continuous therapy.

The possibility of the development of hematuria from uric acid crystals or calculi must be seriously considered. We have recognized the phenomenon in only one patient, but we may have overlooked transient episodes in other patients. When the initial uric acid level is very high—12 to 15 mg. per 100 cc.—the daily excretion may be of the order of 2 gm. This quantity of urate, even in urine volumes of 2,000 cc., is far too great to be held in solution at the usual pH of urine.[20] Therefore, we have recommended a large fluid intake and the ingestion of about 8 gm. of sodium bicarbonate daily during probenecid therapy. When the initial serum uric acid level is very high, it is probably safer to begin treatment at 1 gm. of probenecid per day. However, we have had no experience with that dosage.

S., and Nobe, C.: The Influence of Urinary pH on the Renal Excretion of Salicyl Derivatives During Aspirin Therapy, J. Lab. & Clin. Med. 35:237-248 (Feb.) 1950.

The failure of probenecid therapy to lower the serum urate level in three patients with diminished renal function must be further explored in both gouty and nongouty patients. It is important to determine whether renal insufficiency was actually the cause of failure of probenecid action in these cases and, if so, what the nature and degree of the renal defect must be to cause this failure. Such experiments are now being carried out.

SUMMARY

The therapeutic potentialities of probenecid in the treatment of recurrent gout and chronic gouty arthritis were studied in 20 patients. Ten were followed for periods of five to seven and a half months. With a dose of 2 gm. daily, serum uric acid fell within 72 hours to an average of 55% of the control level. This was associated with an initial increase in urate excretion of 35% to 200%. Urate clearances remained increased two to fourfold with continued probenecid administration.

In three patients with decreased renal function, probenecid therapy produced no fall in the serum uric acid level. When acetylsalicylic acid was given simultaneously with probenecid, the action of the latter in lowering the serum uric acid level was completely annulled but was restored when acetylsalicylic acid therapy was discontinued.

Probenecid therapy proved of greatest benefit in chronic gouty arthritis. Joint movement improved progressively in all patients; pain and swelling subsided. Acute attacks of gout developed in some patients soon after treatment was started, but their incidence diminished with continued therapy. No significant or consistent changes occurred in the serum electrolyte concentrations during prolonged therapy. No abnormalities in blood cell distribution were found. Results of hepatic and renal function tests remained normal. In one patient mild hematuria occurred from urate crystals during the first stage of treatment.

BLUEPRINT FOR IMPROVED PHYSICIAN-PATIENT RELATIONS

Chester L. Roberts, M.D., Glendale, Calif.

The public is becoming impatient with the physician who is merely a good technician. Years ago, the patient had a beloved family physician to whom he could take all of his problems, medical and personal. Today, advances in medical and surgical methods assure the patient of improved physical treatment, but he often finds that he is no longer treated as an individual with a disease but as a "case" of a certain disease. Worse still, if the patient suffers from one of the many conditions that cause bothersome, disabling aches and pains that cannot be analyzed medically nor classified definitely into one category or another, the illness is too often considered to be psychosomatic.

Every patient who seeks medical help for the relief of painful symptoms is entitled to an unhurried and sympathetic hearing, whether his problems be primarily physiological, primarily psychological, or a combination of the two. Patients with organic problems are often in need of a strong dependable relationship, a framework within which reassurance can be offered to offset or alleviate the anxiety aroused by the patient's fears. On the other hand, patients whose symptoms are mildly or markedly excessive in view of the physical findings often experience a great deal of relief in sharing emotional problems with their physicians.

Beginnings of the relationship between the physician and the patient are laid even before the initial contact with the physician. The impress of the physician's personality can be felt the moment the patient steps into the reception room. Favorable first impressions are most important.

OFFICE MIRRORS THE PHYSICIAN'S ATTITUDE

The patient should be regarded as a guest, not as an interruption of the receptionist's work. The receptionist, like all persons employed by the physician, will take her cue from her employer: if he apparently welcomes the patient's visit, the receptionist will do so; if the physician is annoyed at the interruption, that attitude is passed on by the girl at the front desk.

Someone should be on hand to greet each patient. The newcomer should be made to feel welcome; he should be smiled at and spoken to cordially, by name if he has been in before. If the patient's name is foreign or difficult to pronounce, the receptionist should record the correct pronunciation of the name on the folder or card for the physician's use and for future reference. Use of the patient's name shows recognition and appreciation.

The patient should be given some idea of the probable wait before he can see the physician. If the physician has been called out, the patient should be informed of this, and the receptionist might suggest that the patient use the time for having coffee or shopping. If, for any reason, the physician will be unable to see the patient at the appointed time, every effort should be made to reach the patient at the earliest possible moment by telephone or even by telegram. The physician's staff should show that they and the physician appreciate the fact that the patient's time, too, is valuable.

The physician himself can do much to make the patients awaiting their turns in the reception room feel his friendly interest. A smile or nod in recognition and welcome as he catches sight of an old patient will accomplish wonders. A high degree of intelligence is needed to increase the patient's feeling of his own individuality and to convince him that his best interests are being respected. The physician should insist that the office nurse usher in patients in their turn, rich and poor alike. Patients should not be turned away because they have neglected to make appointments if they can be fitted into the appointment schedule.

Special provision should be made for the handling of exceptional patients, such as the patient with facial deformity who shuns contact with others, the patient who coughs and sneezes, the drunk or belligerent patient, and the talkative, forgetful, and argumentative elderly patient who needs kindly and tactful attention.

Patients expect a sense of reserve on the part of the physician and his employees. If the receptionist or office nurse gossips and discusses the idiosyncrasies of the man or woman who has just left the office, the patient receives the impression that the physician, too, is probably too talkative about his patient's concerns. If charts are left out in the open where they can be studied by all comers, and, if names are used loosely in telephone reports of laboratory or physical findings, patients are uneasy. Closed doors add to feelings of privacy. The waiting room serves as the physician's showcase, and the secretary or receptionist should be considered a mirror of the doctor himself.

CONCEPT OF THE "PERSONAL PHYSICIAN"

Men in medical practice today fall into one of two categories: the specialist and the general practitioner. The specialist publicly announces his intention to limit his practice to some specialty, possibly to the study of one organ or one disease process. The general practitioner, on the other hand, purports to fill the place of the beloved old-time family physician—a family physician, however, with modern techniques and knowledge.

The public is confused by the multiplicity of medical specialities, yet it has come to think of the general practitioner as a medical drudge who can handle small, routine medical problems adequately but is hardly to be trusted with serious medical disease. The public has become very specialist minded.

Ernest Dichter, in his report to the Committee on Medical Economics of the California Medical Association, has suggested that the term "general practitioner," to which such disapprobation has attached, should be replaced by the concept of the "personal physician," a specialist in medical management whose job it is to administer, secure, and supervise the best available care for all medical and surgical problems. While the specialist limits his study to one disease or one organ, the personal physician gives his attention to the disease process in the whole person. Moreover, he sees the whole person operating in a specific family set-up and within a definite socioeconomic framework.

For example, the specialist, focusing his attention on the effects of tension and overwork on a single organ or group of organs might say, "Stop worrying. Go to a beach resort for a period of at least three months, and rest up." This advice, while practicable for patient A or B, may be wholly unrealizable when applied to patient C, who is barely able to support herself and her bedridden mother. The personal physician, knowing the circumstances, that a three month holiday is out of the question and that the suggestion would only add to the patient's distress and give her additional cause for worry, might suggest a more practical alternative in the light of the patient's situation, such as a rearrangement of work hours, frequent rest periods, week-ends in bed, and the like. Knowing the patient's background, the personal physician is able to sift his observations with shrewdness and judgment not always given to the specialist.

SYMPATHETIC HANDLING IMPORTANT

In the physician's inner sanctum, the physician-patient relationship is defined as the physician listens with calm, unhurried, and sympathetic attitude to the patient's version of the problem. The physician will often learn much in this way that he might miss in the more direct question-and-answer type of interview. Kindness and tactfulness are most important. It is not easy to be pleasant as one nears the end of a long day, but every patient needs good humor, sympathy and a quiet manner, no matter how weary or upset the physician may be personally. At times, high tension in the patient may be relaxed by a pleasant bit of conversation or a momentary diversion.

The physician should concentrate his entire attention on the patient during the consultation. His desk should be free from distracting material. If possible, he should refrain from answering the telephone while seeing a patient. Patients should receive special handling with reference to age and position. The older man expands in an atmosphere of respect and deference; the aging woman objects to any act that may emphasize her frailty. Adolescent youngsters object to being "treated like children."

Careful and efficient physical examination and performance of indicated laboratory procedures impart to the patient the feeling that a sympathetic and capable friend is in control of the situation. If the examination is made with authority and assurance, the procedure itself has psychotherapeutic value and the medications prescribed often acquire psychological meaning that increases their efficiency beyond their pharmacologic value.

A common criticism of the medical profession is that the physician does not explain the patient's illness to him. Explanations need not be lengthy or complicated. Simple explanations couched in terms the patient can understand and possibly accompanied by simple line diagrams, are sufficient. Explanations should include the following: (1) what the condition involves; (2) the chances of recovery; (3) the duration of hospitalization; (4) the length of convalescence; (5) the probable cost; and (6) how soon normal activities can be resumed. The patient should be invited to become an active participant in the whole treatment.

False hopes should not be aroused. Patients usually react to bad news more favorably than members of the family. If the patient's fears are unfounded, the physician should not laugh at the fears; he should explain them away instead. Patients whose symptoms cannot be explained by physical findings or who report symptoms out of all proportion to observable pathological conditions often make speedy recoveries after the nature of their illness is explained to them. Physicians should be slow to dismiss an illness as psychosomatic. Apparently psychotains viable organisms (dormant) even though nutrients are absent. Controls in table 3 clearly illustrate that the methods of sanitization employed by hospitals are often inadequate and are therefore conducive to postoperative infections that are usually attributed to other causes.

Particular significance was placed upon the transmission of tuberculosis bacilli, and with this in mind studies were initiated to depict this possibility. Acid-fast Mycobacterium tuberculosis var. hominis and Myco. tuberculosis var. bovis were never shown to be present in apparatus examined; however, patients who were known to harbor tuberculosis bacilli were not anesthetized in any of the cases. Although tuberculosis bacilli were absent, several pathogenic species of microbes were isolated and identified. Pyogenic Micrococcus, Streptococcus, and Pseudomonas aeruginosa were frequently present. These organisms are likely to become secondary invaders and in addition produce serious primary infections in their own right.

Saprophytic micrococci and bacilli were constantly isolated, and even though they are nonpathogenic per se they are occasionally incriminated as secondary invaders complicating more acute diseases. Species of organisms of the genera Bacillus (B. subtilis) and Micrococcus (M. citreus) depict secondary infective agents commonly observed. Viruses were not included in this report although they are certainly transmitted by anesthetizing apparatus: Virus infections would appear to be the most frequently transmitted agents owing to their submicroscopic size and distribution.

Several species of unidentified hemolytic microbes of the genera Micrococcus, Streptococcus, and Bacillus were represented, but their relation or etiology to disease is dubious. These organisms occur with greater frequency in the ether-air tubes than in the rebreathing bags. Aspergillus organisms and one other unidentified organism were obtained in tremendous numbers from the rebreathing bags of some of the apparatus tested. This may be due to the collection of debris in the rebreathing bags, which serves as an excellent pabulum, or to the resistance of the fungal spore. Table 4 will elucidate more emphatically the type of genera and species that have been isolated and identified.

Table 4.—*Species of Microorganisms Identified from Anesthetizing Apparatus*

- Bacillus species
  - B. subtilis
  - B. mycoides
- Micrococcus species
  - M. citreus
  - M. pyogenes var. aureus
  - M. pyogenes var. albus
- Streptococcus species
  - Str. pyogenes
- Gram-negative bacilli
- Aspergillus species
- Alternaria species
- One unidentified genus
- Pseudomonas species
  - Ps. aeruginosa
- Flavobacterium species
- Sarcina species
  - S. lutea
- Candida albicans

Apparatus removed from the patient and immediately sanitized according to routine methods employed (rinsing with tap water) were found to contain viable and dangerous organisms; however, sanitization with water and pHisoderm® with 3% hexachlorophene proved to be an appropriate procedure. This method is suggested for sanitizing anesthetizing tubes and rebreathing bags prior to or immediately after use. Table 5 illustrates the effect of cleansing methods upon the resulting degree of sanitization.

SUMMARY

The passage of microorganisms from the patient to the rebreathing bag of the apparatus used for administering gaseous anesthetics occurs with unrecognized frequency. If the apparatus is not properly sanitized, pathogens may be disseminated to subsequent patients. One must not come to rely upon the removal of microbes by the soda lime tower of the apparatus. These studies demonstrate beyond doubt the passage of microbes from the patient through the tower to the rebreathing bag.

Table 5.—*Effect of pHisoderm® Containing 3% Hexachlorophene on the Degree of Sanitization*

Apparatus Tested	Total Bacterial Counts	
	Tube	Rebreathing Bag
D-1	200	200
D-2	1,300	800
D-3	200	100
D-4	500	600

From a preliminary survey of the procedure for administering gaseous anesthetics and the sanitization of used apparatus, it is apparent that more appropriate methods are required. Merely rinsing with water is not sufficient and is not advocated; however, a substantial reduction in the microbial count is obtained by cleansing with pHisoderm® containing 3% hexachlorophene. The pHisoderm® can then be removed by rinsing with water. Frequent cleansing of the rebreathing bag prevents the accumulation of debris, which serves as an excellent medium for the growth of microorganisms. Cognizance should be taken of the data presented in this report, and thus another possible source of disease transmission can be eliminated.

Sir Charles Scott Sherrington (1859-1952).—Running throughout all of Sherrington's work is a broad philosophy to which he seldom referred except by indirection. But it led Leon Asher, when the University of Berne conferred an honorary degree upon Sherrington in 1931, to refer to him as "the philosopher of the nervous system." This brief citation brought a thundering ovation from the huge audience of neurologists, representing virtually every nation of the world, who had gathered at Berne for the first International Neurological Congress. . . . Through the years of his remarkable scientific productivity Sir Charles had continued his interest in poetry, art, and the cultural backgrounds of medicine. It was not widely known that he was an accomplished classical scholar, but perusal of his more recent books, such as "*Man on His Nature*" and more particularly his "Endeavour of Jean Fernel," will clearly reveal his familiarity with classical texts in which he had always found so much pleasure and relaxation. In preparing for the Fernel, Sir Charles had immersed himself in Galen and the contemporary literature of sixteenth century France. The result is a work of ripe scholarship that would be the envy of any scholar of the period who might have devoted an entire life to the subject. . . . It has been said of him that his genius lay in his extraordinary capacity for translating the facts of morphology into physiological language. This he had done with notable clarity at the spinal and medullary levels; he also elucidated the organization and somatic functions of the cerebral cortex, but he disclaimed any credit for advancing knowledge of mental functions. When discussing the brain as an organ of the mind, Sir Charles insisted, as recently as 1947, that we are no farther along today in accounting for mental processes in physiological terms than was Aristotle two thousand years ago.—*J. F. Fulton, M.D., Sir Charles Scott Sherrington, O.M. (1857-1952), Journal of Neurophysiology*, May, 1952.

FROSTBITE: AN ANALYSIS OF SEVENTY-ONE CASES

Edward A. Edwards, M.D.
and
Major Roy W. Leeper, United States Army, Boston

Though frostbite is a well-known and serious malady, knowledge of its pathogenesis and of the optimal methods of its management is far from complete. This is due in large part to the paucity of cases coming under the scrutiny of any single group of investigators. The war in Korea in the winter of 1950-1951 resulted in a high incidence of frostbite among our troops. Seventy-one of these patients have been cared for at the Murphy Army Hospital and form the basis for this report. All these soldiers suffered from true freezing of the hands or feet, with resultant necrosis involving at least small areas of deep tissues, and with gangrene of the digits and forepart of the feet in several patients. No cases of cold injury short of this extent are included.

The climatic environment and the combat situation combined to form the epidemiological background of the disease. Most of the patients were frostbitten in north central Korea in the week between Nov. 27 and Dec. 3, 1950. According to information supplied by the Air Force, the temperature in that locality and time reached minimal levels of 12 F. The wind attained a maximal velocity of 20 miles per hour. Our patients were mainly infantrymen. Their protection against the weather was adequate until they were attacked by overwhelming numbers and forced to retreat. The effect of a more stabilized battle line and a more southerly position, which obtained after Dec. 3, served sharply to reduce the incidence of frostbite, though temperatures later dropped as low as -13 F.

The chronology of evacuation is pertinent to the timing of observation and treatment. The time of removal from the field varied from 1 to 11 days after the first onset of symptoms. An aid station was reached in several hours to two days, where the patients usually remained for two to seven days. Further evacuation was by air, the patients arriving at an overseas hospital within a few hours and remaining for about 20 days. Most patients reached the Murphy Hospital three to four weeks after freezing, exceptional cases falling in a range of 17 to 40 days.

We shall describe the clinical picture of the disease, dividing it into acute, subacute, and chronic stages. The acute stage corresponds to the first three or four weeks spent in the overseas medical installations and was characterized by freezing, thawing, exudation, and the initiation of necrosis. Data on this stage were obtained from the patient's history and his medical record. The subacute stage was the one during which the patient was observed at the Murphy Hospital. It was marked by a resolution of the necrosis and the commencement of vasospasm and cutaneous acrosclerosis. From former experience we may expect a chronic stage, consisting of a continuation of the vasospasm and sclerosis, as well as occasional recurrent ulceration.

Data will also be presented bearing on certain unsettled aspects of the frostbite problem, namely, predisposing factors, factors determining severity, the effectiveness of anticoagulant therapy, the recognition of the presence and extent of gangrene, and the late effects of freezing. In 27 patients with severe lesions, special attention was paid to evidence of preexisting cold sensitivity, including examination of the blood for cold agglutinins. The status of the blood vessels was determined, and the Pachon oscillometer was used as an objective check on the examination. The presence and degree of sweating were recorded in several patients through the aid of photography after the ferric chloride and tannic acid reaction.[1] A biopsy of the skin of the extremities was performed in eight patients. Roentgenograms were made of all the involved extremities.

CLINICAL DESCRIPTION

General Data.—The patients numbered 71 and were all men. The majority were 20 to 23 years of age, the range being 18 to 40. In 67 the feet, and in 3 the hands, were the only parts seriously affected. One patient had severe frostbite of both the hands and feet. No instances of freezing of other portions of the body came to our attention. At least superficial necrosis had resulted in all the patients, and gangrene of entire digits in several. Major amputations, comprising those of fingers or of toes and metatarsal heads, were performed in five patients and will be necessary in two more, a total of 10% of all patients. Six more had surgical removal of portions of one or more toes. Finally, in all of the remaining patients, there were at least localized areas of deep necrosis that did not require formal débridement.

At the time of writing of this report 64 patients have recovered, 63 having been sent to duty and 1 discharged for neurosis. Six patients spent 44 to 60 days in the hospital; 50 patients, 61 to 118 days; and 8 patients, 120 to 165 days. Seven patients are still hospitalized.

Predisposition.—The precipitation of the disease in individual cases appeared related either to an exceptional aggravation of the environmental influence or to some predisposition in the soldier himself. Examples of environmental factors noted included removal of gloves or shoes after wounding, accidental wetting of the feet, and exceptional immobility. Three illustrative cases may be cited.

CASE 1.—A 20-year-old infantryman, on the line for several weeks, suffered no ill effects till he received multiple shell fragment wounds of his left forearm and right hand on Nov. 28, 1950. He could now no longer wear his gloves. In the next few days, continuing a retreat on foot, he felt numbness and throb-

[1] Silverman, J. J., and Powell, V. E.: A Simple Technic for Outlining the Sweat Pattern, War Med. 7: 178, 1945.

bing in the hands. On Dec. 2 he suffered a perforating gunshot wound of the middle of the left foot. He crawled through the snow on hands and knees for a few hundred yards, with the hands and left foot exposed. At a first aid station, one-half hour after the second wounding, the hands and feet were observed to be cyanotic, blistered, and swollen. On Dec. 5 he arrived at a hospital, where stellate and lumbar sympathetic blocks were performed; but, despite this, mummification of all the fingers, the left great toe, the ball of the left foot, and the tips of the second, third, and fourth left toes ensued. Only bleb formation and superficial necrosis occurred in the right foot.

Amputation of the fingers and distal part of the thumb of both hands and of the left great toe and metatarsal head was performed on Jan. 25, 1951. Both hands now show residual loss of ulnar blood flow, this being more marked in the left. The pedal pulses are normal, but the feet are cold, sweaty, and cyanotic, and the skin is somewhat rigid.

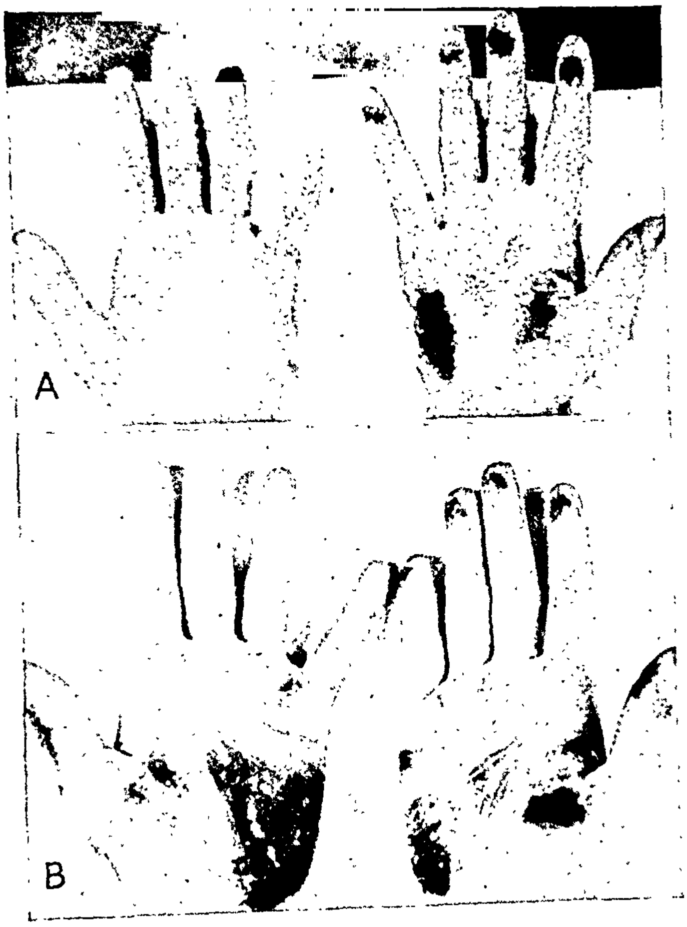

Fig. 1.—The sweat pattern in the hyperemic and in the vasospastic stages, outlined by ferric chloride and tannic acid. The hands shown are those of the patient in case 3, *A*, 5 weeks, and *B*, 14 weeks, after freezing. In the hyperemic stage the left hand (*A*), more severely frozen, shows none of the sweat reaction. The sweating of the right hand is increased. The left hand has entered on the cold hyperhidrotic stage (*B*), with excessive sweating proximally, but with failure of sweating in the distal, most seriously injured parts. The tapering, shiny appearance of the left fingers is characteristic of the acrosclerosis. Sweating, perhaps in increased amount, is expected to return later in the fingers of the left hand.

Case 2.—This soldier, surrounded by the enemy, hid in caves from Nov. 2 to Nov. 13, 1950. He was well clad but had no gloves. On Nov. 4 he wet his feet in a river. He had no fire for food or warming and did not change his socks. Numbness and pain of the feet resulted. When rescued on Nov. 13, he was found to have redness of the feet, without swelling, and black, dry toes. He reached a hospital Dec. 1, where he received 100 mg. 2-benzyl-2-imidazoline hydrochloride (priscoline®) daily. Bishydroxycoumarin (dicumarol®) was also given from Dec. 6 to Dec. 11. Gangrene of all the toes necessitated bilateral transmetarsal amputations on Dec. 27.

No history of previous sensitivity to cold was elicited. Also, the patient was certain he had not frozen his hands; nevertheless, the hands were cold and cyanotic, and there was moderate pterygium of the fingernails. The feet were similarly cold and cyanotic, to above the ankle on the left and to the middle of the leg on the right. The skin of the feet was rigid and smooth. The peripheral pulses were normal. The patient was comfortable, and it was decided to give him a trial of activity.

Case 3.—An 18-year-old infantryman found himself surrounded by the enemy on Jan. 1, 1951. He was in a foxhole, with his rifle at the ready for 12 continuous hours. In this position the left hand rested on the snow, while the right hand was at the trigger close to the body and lower in the foxhole. In spite of the protection of ski mittens, the left hand became numb and stiff. The next day he reported at a first aid station, where the left hand was found to be white and cold. On the third day it was blistered. On his admission to a hospital Jan. 7 he was given 15 intravenous injections of procaine and nicotinic acid. The blisters formed thimble-like eschars, and the nails blackened. Very slight vesiculation and superficial eschars were found only at the very tips of the fingers of the right hand. The feet were slightly uncomfortable but showed no objective changes.

On examination Feb. 2, it was seen that eschars of both hands had separated. The nails of the left hand, now black, were being shed, and the left hand itself had the characteristics of a "trench foot," being extremely hot, red, swollen, and dry. The right hand was in vasospasm, with marked sweating. The peripheral pulses were normal. Nine weeks later the left hand had become cooler, marked sclerodactyly had developed, and new nails were growing. Sweating had returned everywhere except to the fingertips (fig. 1).

Twenty-seven patients, including those with the most extensive gangrene, were studied with special reference to personal factors that might have predisposed to cold injury. Physical signs taken to indicate the presence of vasospastic disease were coldness, cyanosis, sweating, pterygium of the fingernails (widened cuticles),[2] and rigidity and smoothness of the skin over the digits and the dorsa of the hands and feet. When patients were observed early, and when they could remember the chronic presence of one or more of the signs, a diagnosis was made of the existence of vasospastic disease prior to the frostbite. When signs developed several weeks after freezing, they were interpreted as effects of the cold injury. A history of previous frostbite or trench foot, with residual sensitivity to cold and excessive sweating, was obtained in three patients.

Case 4.—A 25-year-old soldier on Jan. 14, 1951, suffered frostbite of moderate severity in the left foot only. Significant in his history was frostbite of the same foot in January, 1950, while he was a ski trooper with the Army in Alaska. Freezing had been attributed to excessive tightness of a leather strap across the ankle, and he had been hospitalized till July, 1950. Since then the left foot had been cold and sweaty, and painful in cold weather. The patient was exceptional in that he smoked but rarely.

Examination showed an eschar of the left foot and toes that was superficial everywhere except at the very tips of the first and second toes. The foot was cold and sweaty. The right foot and both hands were slightly cool. The pulses were all intact. A left lumbar sympathectomy was performed on Feb. 9, 1951. Progress was satisfactory, and the foot was healed and comfortable by March 30.

Nine patients gave a prior history of coldness, either constant or episodic, and two also had hyperhydrosis. In two additional patients, hyperhydrosis was the only symptom. Cold isoagglutinins were found in only one patient. Whether the presence of isoagglutinins played any part in the frostbite in this person could not be determined. No examination was made for cryoglobulins. No patient gave any history suggestive of cold allergy.

---

[2] Edwards, E. A.: Nail Changes in Functional and Organic Arterial Disease, New England J. Med. 239: 362, 1948.

The group of 27 patients was questioned as to their use of tobacco. Twenty were steady smokers of 10 to 30 cigarettes a day. Of the three patients who smoked infrequently, never using more than five cigarettes a day, two had other predispositions to freezing (previous frostbite in one and cold agglutinins in the other), while a third had suffered only minor effects from the frostbite.

Wounding by gunshot or shell fragment seemed clearly to precipitate freezing in six patients. Freezing had either not occurred until the injury or was greatly intensified by it. It must be noted, however, that two of the six patients had suffered from chronic vasospasm and sweating and that a third had suffered from prior frostbite.

Case 5.—For seven days, ending Dec. 1, 1950, this 23-year-old man was in continuous combat, with no shelter or hot food. The feet were sweaty and soon became numb. On Dec. 1 he received two gunshot wounds, one bullet passing through the superficial tissues about the left knee, the other perforating the right side of the chest, with hemoptysis and subcutaneous emphysema. He was in shock and unconscious during evacuation by truck. At the aid station, on Dec. 2, the feet were found to be "dead white," swollen, and blistered. On Dec. 4, when he reached a hospital, the toes were black and the feet sweaty and cyanotic. His wounds were débrided and the chest closed. Whiskey was given daily.

When seen Jan. 5, 1951, he was observed to have gangrene of the tips of the toes and the distal third of the left great toe. The nails of the right second, third, fourth, and fifth toes had been shed, and the others were dark. The right dorsalis pedis and posterior tibial pulses were of good quality. On the left side the dorsalis pedis could not be felt. There was extreme sweating and coldness of the feet, but the toes did not sweat. A roentgenogram revealed extensive demineralization of the metatarsal heads of the left foot. The hands showed pronounced sweating, coldness, rigidity of skin, and pterygium formation. The patient stated that the coldness, sweating, and enlarged cuticles had been known to him since youth. Paravertebral blocks and intravenous injections of procaine failed to hasten healing or diminish the pain in the left great toe. A left lumbar sympathectomy Jan. 28 resulted in good vasodilatation. After the left great toe was amputated, healing was prompt.

Clinical Course and Management.—1. Acute stage: Data on the initial period of the disease were obtained from the patients and their medical records. The universal immediate symptom was numbness of the affected parts, sometimes preceded by a prickling sensation. Before thawing, the parts were white; after thawing, however, redness, swelling, moderate heat, and a burning sensation were noted. These symptoms were apparently much milder and more transient than those seen in trench foot and usually required no sedation. Blistering, with the formation of large bullae, was also seen within a day or two of thawing. The blisters were at first filled with clear yellow fluid, but this became hemorrhagic within three to five days. A similar process apparently took place between the nail plates and their beds, for hemorrhage occurred beneath many of the nails, giving them a black appearance. Some of these nails were shed within several days, others after a few weeks, as they were pushed forward by a regenerating nail plate. The parts were described as turning black about the fifth day. The blistering and discoloration were distributed over wide zones of the digits and of the hands and feet. The extent of this change bore no relation to the later demarcation of deep necrosis or gangrene (fig. 2).

Thawing of the extremities was ordinarily not possible until the patient arrived at the aid station, because continued freezing often occurred during evacuation from the field. Once the patient was in the aid station, thawing was usually allowed to continue in the room atmosphere. Other treatment consisted only of dressings, tetanus toxoid, and penicillin. Treatment at the overseas hospitals almost invariably included the use of vasodilator substances. About two-thirds of the patients received procaine hydrochloride intravenously in a dose of 1 gm. in 1,000 cc. of isotonic sodium chloride solution, which was repeated daily up to 15 doses. Nicotinic acid, 300 mg. a day, was given alone or with the procaine to about the same number of patients, while priscoline® and whiskey were each used sporadically. Sympathetic nerve block was performed in only four patients. Anticoagulants were used in only two patients, one receiving heparin during the first four days, another bishydroxycoumarin for five days one month after freezing. Both suffered extensive gangrene.

2. Subacute stage: Necrosis was the presenting problem on admission of the patients to the Murphy Hospital in about the third week of the disease. Pain was minimal but was increased when infection was present. A black eschar was present over variable portions of the toes and feet, and in three instances over the fingers and hands. In two patients necrosis involved the upper heel, penetrating the insertion of the Achilles tendon. Mummification of gangrenous digits was beginning. Infection was usually minor. The extent of true gangrene could usually not be accurately determined till about the sixth week, since even the superficial portions of the eschar required about four weeks for their separation.

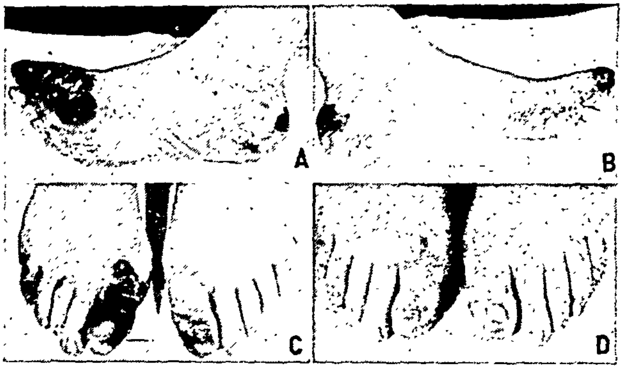

Fig. 2.—Necrosis, resolution, and initiation of acrosclerosis. *A, B,* and *C,* three weeks after freezing, show the extent of black eschar. In *D,* 12 weeks after freezing, the slough has separated, disclosing the necrosis to have been superficial. The great toes are, however, shrunken, with tight, rigid skin and regenerating stubby nails. The sclerosis is less pronounced over the other toes and on the dorsa of the feet.

The duration of freezing after the initial symptoms were noted was probably the most significant single factor in determining the severity of tissue damage. When freezing lasted less than one day, the deep necrosis was usually minor in extent; when it lasted two days or more, at least parts of the digits were lost. Patients who were predisposed to freezing in general suffered severer effects than the others. Wounding in the limb or elsewhere was the most significant factor in this regard.

Roentgen studies of the bones proved of limited value. The bones of gangrenous digits revealed no change at all, evidently because of the lack of metabolic exchange (fig. 3). More localized areas of soft tissue necrosis were occasionally associated with absorption in the underlying bone, with an irregular line of the cortex and a disorganization of the trabeculae, which appeared reticular in arrangement (fig. 4). The typical gross disruption of osteomyelitis was seen beneath badly infected lesions. The atrophy of disuse was seen late, usually about the eighth week of the disease, and it was manifested by a glassy appearance of the metatarsal heads and of the bases of the proximal phalanges (fig. 3).

The occlusion of a peripheral artery was probably indicated by the absence of the dorsalis pedis pulsation on one side, which was noted in 3 patients out of the specially examined group of 27. The lack of pulsation was accompanied by an asymmetry of the oscillometric reading. Only one patient of the three had suffered from previous cold injury.

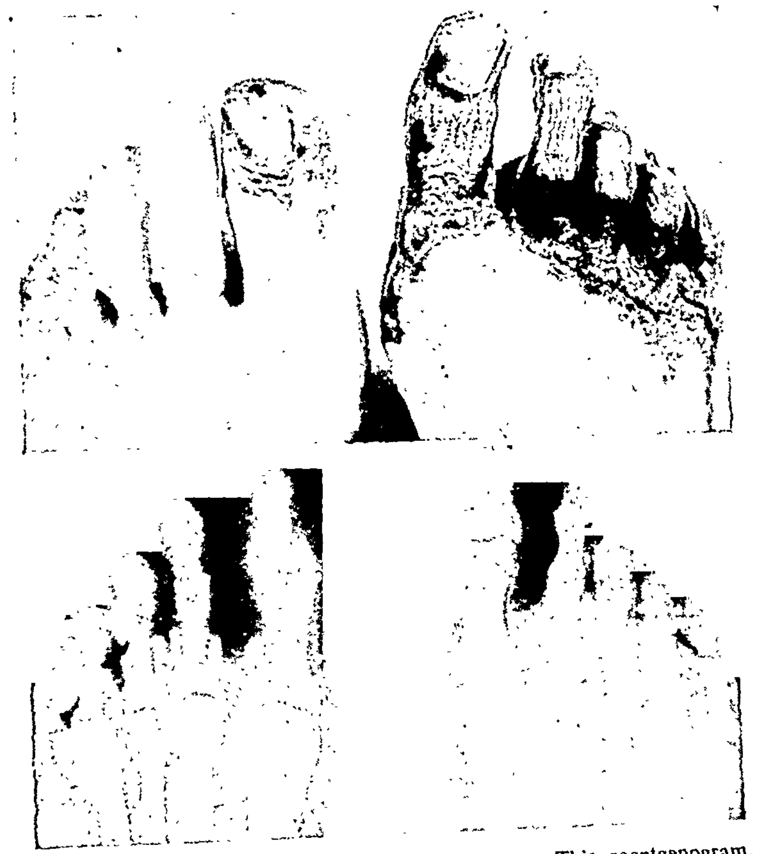

Fig. 3.—Gangrene and the roentgen appearance. This roentgenogram, made eight weeks after freezing, reveals no change either in the gangrenous toes or in the toes showing superficial necrosis. On both sides there is absorption of the heads of the metatarsals and of the bases of the proximal phalanges.

Sympathetic paralysis with hyperemia and dryness of the extremities was seen in a few hands and feet in which the freezing had been only moderate (fig. 1). In some patients with extensive necrosis, a brief hyperemic phase had been noted in the acute stage. Sweating was absent in cold areas from which a fairly deep eschar had separated. In these areas atrophy of the sweat glands may have been important. The absence of sweating, whether or not associated with hyperemia, was often replaced by excessive perspiration as vasospasm supervened.

Vasospasm has already been described, and the point was made that this change often existed in some patients prior to the freezing, while in others the vasospasm was evidently the result of the frostbite, becoming manifest in several weeks. When only one limb had been frozen, the presence of the vessel change in that limb alone supported the contention of its causation by the freezing.

Vasospasm was a common effect in the subacute stage, although it was not extreme in degree unless the patient had suffered from prior chronic vasospasm.

Neurological changes consisting of sensory loss were evident in all cases. The loss of sensation was never absolute except over gangrenous parts. It was "glove" or "stocking" in extent, the hypesthesia being most pronounced distally, with normal sensation present at the ankle or wrist. The sensations most affected were light touch and fine temperature discrimination. A light pinprick was often not felt in the most distal parts of the limb, but a stronger pinprick was discernible and pain could be elicited on strong pressure. Deep pressure and vibration sense were not impaired. The neurological findings were consistent with the lack of pain as a complaint during the early weeks of the subacute stage. Pain was felt, however, when active infection was present, and pain was a frequent complaint after the eighth week of the disease, at a time when sensory acuity had returned. The evidence for sympathetic paralysis, and the vascular changes and sweating indicative of sympathetic irritation, have already been discussed.

Cutaneous atrophy and sclerosis were evident over areas where superficial necrosis had been present and to a lesser extent proximally, to the line of the ankle and wrist. The signs of this acrosclerosis became apparent about the sixth week of the disease but certainly progressed somewhat for an additional four weeks. They consisted of shortening of the digits, with thinning of the digital pulp pads; irregularity, thickening, and shortening of the nails; loss of normal wrinkling and surface friction of the skin on the dorsa of the digits, hands, and feet; and rigidity of the subcutaneous tissue (fig. 1 and 2). The changes were those ordinarily described as acrosclerosis. Vasospasm was apparently constantly associated with these changes, but the two processes were not proportional in degree.

A biopsy of the skin was performed in eight patients, specimens being taken from toes or dorsa of the feet, and in two patients of the hands as well. Since the site of biopsy was considerably proximal to the gangrene, the histological examination was more significant as showing the changes of acrosclerosis than as revealing the lesions leading to necrosis. The epidermis was thin, with flattening of the basal papillae. Immediately beneath the epidermis the collagen appeared light, but in the deeper cutis and in the subcutaneous tissue the collagen was heavier than usual. The elastic tissue was fragmented. The sweat glands appeared atrophied in some areas. Small blood vessels showed swelling of the endothelium, and here and there intimal proliferation could be seen. In one patient this process had obliterated the lumen of a small artery. Some nerve fibers showed degeneration with fibroblastic replacement. In general, inflammatory response and fibroblastic proliferation were notably minimal.

Treatment was directed toward the following aspects of the subacute state: (1) prevention and treatment of infection, (2) release of vasospasm, (3) débridement of necrosis, and (4) amputation of gangrenous parts. The affected parts were kept covered with sterile dressings, which were moist if infection was prominent and dry otherwise. Penicillin was used at least initially in all patients. Vasodilating agents (priscoline® or beta-pyridilcarbinoltartrate [roniacol®]) were given to those showing much vasospasm. There was no clear-cut evidence that the drugs hastened healing. Lumbar sympathectomy was performed in six patients in whom preexisting vasospasm had been, and still was, severe. This included the three persons in whom one dorsalis pedis pulse was missing. Sympathectomy was distinctly helpful in speeding healing as well as in giving a warm, comfortable limb.

Removal of the superficial eschar was aided by cutting away loosened portions in order to allow an earlier delineation of the extent of the deep necrosis. Deep necrotic tissue was likewise removed from time to time as demarcation became evident, exposed portions of bone being rongeured back. Amputations, when necessary, were performed close to the line of demarcation, with satisfactory healing.

3. Chronic stage: The changes we know to be characteristic of the chronic stage of frostbite could already be observed in most of our patients during their hospital stay. The sclerodactyly noted several weeks after freezing often increased as healing took place. The affected digits thus became shortened, with atrophy of the digital pad, with an irregular nail plate, and with the smooth, rigid skin of the digit and hand or foot already described (fig. 1 and 2). Vasospasm and hyperhidrosis gradually disappeared in some limbs but remained prominent in others, especially where cold sensitivity had existed prior to freezing. Pain was now a more frequent complaint, not only in the scars resulting from the necrosis but also in the more proximal parts.

COMMENT

Etiology.—Stated in simplest terms, an extremity is frozen when its loss of heat is greater than can be offset by local heat production or by local warming from the blood perfusing the limb. As regards heat loss, both the temperature of the ambient air and the wind velocity are important. Humidity is so low at freezing temperatures as to be of negligible importance. Wetting of the foot gear, either by perspiration or by accidental immersion, greatly increases the tendency to freezing, since water transfers heat 23 times more readily than air.

The effective blood perfusion of the limbs is diminished via peripheral vasoconstriction from a variety of causes incident to adverse combat conditions. Even with so-called adequate clothing, a man exposed to severe winter weather often suffers considerable chilling and peripheral vasoconstriction. Under ordinary circumstances this chilling is not allowed to continued uninterrupted for many hours, being relieved by the general warming and vasodilatation occasioned by eating, especially when the food is hot, and by intermittent shelter and warming, especially during sleep. When this relief from chilling is denied, vasoconstriction is unrelieved. Hunger, exhaustion, and anxiety all increase the vasoconstriction. The vasoconstrictive effects of tobacco smoking may aid in this process and help to induce freezing. Wounding appears to be an effective precipitant of freezing, adding the vasoconstriction of shock and hemorrhage, loss of blood volume, wetting of the part with blood, and bodily immobility. Blair states that 35% of all cold injury patients seen in the army had been wounded prior to the development of the frostbite.[3]

It is widely known, in a general way, that persons vary in their response to cold. We have noted more specifically that many of our patients had suffered from chronic vasospasm and that a few had suffered previous freezing or trench foot. It would seem that soldiers showing stigmas of cold sensitivity, or with a history of previous cold injury, are poor subjects for duty in freezing climates. Further search seems indicated for evidence, in cold injury patients, of the presence of isoagglutinins (cold agglutinins) and cryoglobulins. The role of a low basal metabolism might also be investigated with profit, since it is known that the temperature of the extremities in patients with a low metabolic rate drops lower under adverse conditions, such as tobacco smoking, than does that of patients with a higher rate.[4]

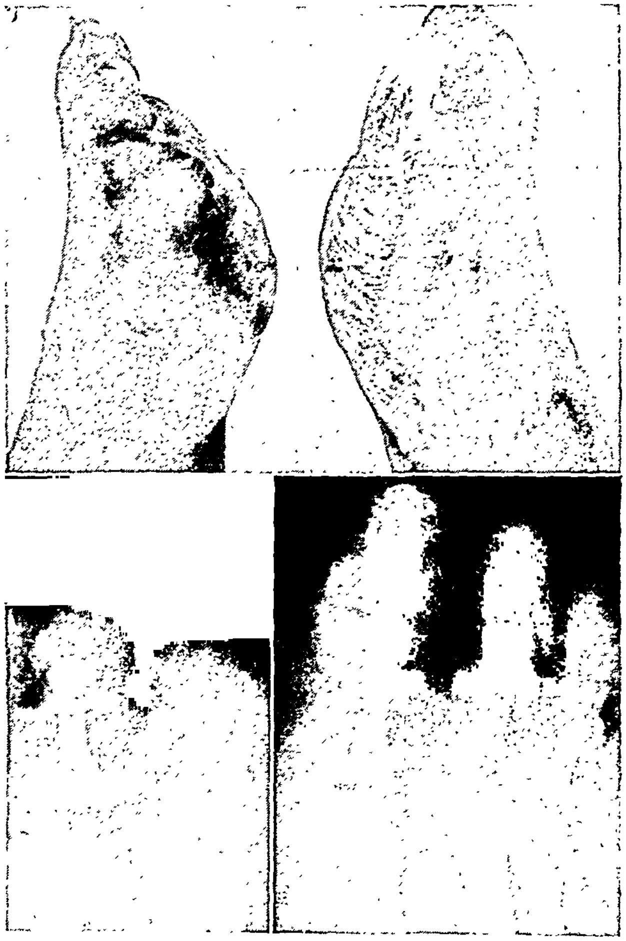

Fig. 4.—Roentgen findings associated with superficial necrosis. The film, made nine weeks after freezing, shows on the right, spotty absorption with disruption of the trabeculae in the head of the metatarsal and in the head of the first phalanx of the great toe (corresponding to the area of maximal injury seen in the photograph). The necrosis of the stump of the previously amputated left great toe was not accompanied by any roentgen change.

Pathogenesis and Treatment.—A brief statement of the mechanisms responsible for the effects of frostbite will suggest the rationale of treatment. Two excellent reviews [5] may be consulted for the present status of our knowledge in this field. It appears that necrosis may be caused by one or more of the following factors: (1) direct injury from the freezing itself, with evidence most striking in the case of muscle[8] and nerve tissue,[6] (2) edema of the hyperemic phase, which ensues soon after thawing,[7] and (3) vascular occlusion by "conglutination" of the blood cells in the vessels in the early hours after thawing, or by larger thrombi in which some fibrin is seen and which develop some days after thawing.[8]

[5] (a) Footnote 3. (b) Kreyberg, L.: Development of Acute Tissue Damage due to Cold, Physiol. Rev. 29: 156, 1949.

Anoxia due to lack of dissociation of oxygen from hemoglobin at low temperatures is probably unimportant in the actually frozen tissue, since its metabolism is adequately depressed. Changes in the blood vessels themselves, consisting of early swelling and vacuolization of the intima, with later changes of proliferation, are known to occur early and to continue into the chronic stage. These changes are probably not responsible for the early necrosis but may cause some of the chronic effects.[9] The duration of exposure, once freezing has commenced, seems of extreme importance in the extent of the subsequent gangrene of the entire part. This was true in the experience of Brahdy,[10] as well as in our present study. Rapid thawing is thought by many to significantly reduce the effects of frostbite.[3] Rapid thawing, as defined by Schumacker and Lempke,[3] consists of immersion of the frozen parts in water at 42 C. They agree with others that temperatures as high as 50 C may be harmful and urge also that, once thawed, the part should be allowed to remain at the cooler level of room temperature. Rosenfeld and his co-workers[11] present the contrary view that rapid thawing increases the necrosis, at least after experimental freezing in the dog. Attempts to diminish the effect of the edema by the use of pressure bandages or casts have not altered the course of the disease. Experimentally edema is increased by early sympathectomy or post-thawing heating, with increase in pain and perhaps in necrosis.[5]

The importance of blood cell stasis and thrombosis in producing ischemia and subsequent necrosis was emphasized by students of the frostbite problem in World War II, notably Greene[8b] and Friedman.[8c] Lange and Boyd[12] utilized visualization by fluorescein to demonstrate that maximal hyperemia of the frozen tissues at 4 hours after thawing is followed by a lack of circulatory exchange at 48 hours. These authors suggested the use of heparin to prevent the red blood cell conglutination responsible for the circulatory stasis. Kreyberg[5b] sums up the considerable evidence that heparin does not prevent the early conglutination. Friedman, Lange, and Weiner[13] have come to agree with this view, but nevertheless hold that heparin will prevent the formation of secondary agglutinative thrombi and is therefore important in preventing necrosis. This group emphasizes that the heparin must be given early and in adequate dosage to prolong the coagulation time uninterruptedly for at least five days after freezing.[14] The available reports on treatment of human cases with anticoagulants seem inconclusive. A further, well-controlled clinical trial with this mode of therapy would appear highly desirable.

Our data support the view that the release of sympathetic tone by medical or surgical means is not useful in the acute stage of frostbite. Indeed, experimental work previously available[15] had suggested that vasodilatation may be harmful at that time. It is in the subacute and chronic stages of the disease, when vasoconstriction is prominent, that release of sympathetic tone would seem effective. Surgical sympathectomy in the subacute stage is particularly desirable when it appears reasonably certain that chronic sequelae would otherwise result. At the present we are unable to predict accurately the future course of the disease in all patients. As a working rule we propose that loss of a major peripheral pulse, or severe chronic vasospasm existing prior to the frostbite, be considered indications for the operation. Indications in the chronic stage include recurrent ulceration or pronounced vasospasm and discomfort that have failed to disappear after the freezing. Judging by experience with veterans of World War II, it would seem that a period of about two years might be considered adequate time for such symptoms to clear spontaneously.

SUMMARY AND CONCLUSIONS

The clinical course of 71 cases of frostbite of the extremities, all showing necrosis, is described. The patients were all soldiers, and the precipitating factor was the adverse combat situation. Personal factors of importance in the causation of the freezing were the existence of chronic vasospasm or hyperhidrosis, previous cold injury, wounding, and possibly tobacco smoking.

The disease is described in three stages: (1) the acute, characterized by the freezing, thawing, blistering, and beginning of necrosis; (2) the subacute, during which the necrosis is resolved and vasospasm and acrosclerosis start; and (3) the chronic, when the vasospasm and acrosclerosis continue and pain and recurrent ulceration may occur. Treatment during the acute stage consisted mainly of administration of antibiotics and sympathicolytic drugs. Anticoagulants were used in only two patients. In the subacute stage use of antibiotics and sympathicolytic drugs was continued, and the eschar was gradually removed. Sympathectomy was done in six patients in whom preexisting vasospasm had been pronounced.

The superficial necrosis was always more extensive than any underlying gangrene, and observation over several weeks was necessary before amputation was performed. Amputations of fingers or of toes at metatarsal levels were necessary in seven patients, while amputations of portions of toes were necessary in six additional patients.

The duration of freezing after initial symptoms was the most important single factor in the extent of necrosis. Patients showing personal predisposition to freezing, especially those wounded, also suffered most severely. The use of sympathicolytic drugs in the acute stage seemed to have no effect on the outcome. Anticoagulants would appear to deserve a more thorough trial, and more data may help in the question of rapid versus slow thawing.

Sympathectomy appeared to hasten healing in the patients operated on in the subacute stage. It would seem to be indicated when severe vasospasm or other vascular disease has existed prior to the freezing or when the frostbite has caused loss of a peripheral pulse. It is not possible to predict accurately which patients will show long-lasting chronic effects. It is suggested that one wait no longer than two years for spontaneous disappearance of symptoms before performing sympathectomy.

METASTASIS OF RECTAL CARCINOID TO THE BROAD LIGAMENT

C. H. Epps, M.D., R. N. White, M.D.
and
E. B. Hanan, M.D., Springfield, Mo.

It is our purpose in reporting this case to call attention to an extremely uncommon tumor of the broad ligament. The tumor in our case proved very confusing as to identity until it was found to be metastatic from a small inconspicuous primary lesion of the rectum.

The adnexae and parametria have been the site of many unusual tumors. Many of these tumors have been difficult to identify as evidenced by the numerous suggested classifications of ovarian tumors. The development of these structures gives rise to innumerable possibilities for different types of tumors and for their appearance in unusual locations. Reports of carcinoids in this region, however, are rare. Stewart and Taylor[1] described a patient with primary carcinoid of the appendix with two metastatic nodules implanted on the pelvic peritoneum; the patient was well 10 years after the removal of the appendix and the two nodules from the cul de sac. Siburg[2] reported a case of carcinoid of the rectum with extensive metastases to sacral and aortic lymph nodes, vertebra, liver, and chest with a rapidly fatal course. Stewart, Willis, and de Saram[3] described two patients with dermoid cysts of the ovary with areas of argentaffin carcinoma, one of whom was well three and one-half years after surgery. We have been unable to find any reported case of carcinoid that resembled an intraligamentary tumor or any case of carcinoid of the rectum with metastasis to this region. We believe that ours is the first reported case of carcinoid of the rectum metastasizing to the broad ligament and also the first reported case of carcinoid of the rectum with known metastasis of four years' duration. Our case is also unusual in that the metastatic tumor was found before the primary tumor in the rectum was discovered, which gave rise to considerable speculation and discussion as to its classification and origin.

As early as 1888 Lubarsch[4] reported two cases of multiple small submucosal cancers of the small bowel composed of nests of uniform cells not resembling cells of the intestinal mucosa, and in 1901 Whipham[5] reported unusual yellow carcinomas of the ileocecal region and referred to 18 cases reported by Kelly, one by Rolleston, and one by Hurdons. Whipham's description of the histological changes was remarkably similar to descriptions by present day authorities, but it was not until 1907 that Oberndorfer,[6] who believed them to originate from the mucosa and to be benign, suggested the term "carcinoid." Saltykow[7] probably reported the first carcinoid of the rectum in 1912. Numerous investigators have objected strenuously to the term carcinoid and have proposed such terms as "argentaffinomas,"[7a] "Kultschitsky cell tumor," and "carcinoma grade 1 (Broders[7b])," but the term carcinoid still prevails. Since Horn and other authorities have demonstrated that not all rectal carcinoids contain argentaffin granules and that some rectal carcinoids contain mucin, it seems that the term carcinoid is probably as good as any, particularly since the malignant potentiality is well recognized but extremely variable.

There are excellent reviews of the literature pertaining to carcinoids of the rectum by Horn,[8] Stout,[9] Pearson

and Fitzgerald,[10] and Pautler and Scotti.[11] Horn's report probably is the most recent and comprehensive; he reports 56 cases, including six of his own. Of the 56 lesions, five were malignant. Since Horn's report, Shepard and co-workers[12] reported two cases of carcinoid of the rectum, both of which were locally invasive but without metastasis. Wilson[13] reported another small carcinoid in the rectum, but in his case there was one metastatic gland at the upper end of the rectum in the mesentery. Early in 1951 Hines and Riddler[14] reported three cases of rectal carcinoids with no mention of metastases, and Mayo and McKee[15] reported two cases of polypoid carcinoids with no known metastases. Seven other cases were mentioned in a paper by Pearson and Fitzgerald,[10b] which were observed at the Memorial Hospital in New York, but no details were given as to location, age, or malignancy. The addition of our case makes a total of 72 cases of rectal carcinoids, in seven of which the lesion was definitely malignant. Some evidence as to the rarity of rectal carcinoids is gained by the fact that Stout[9] found only two cases in 13,809 routine autopsies and Hines and Riddler[14] found only three cases in 30,000 routine proctological examinations.

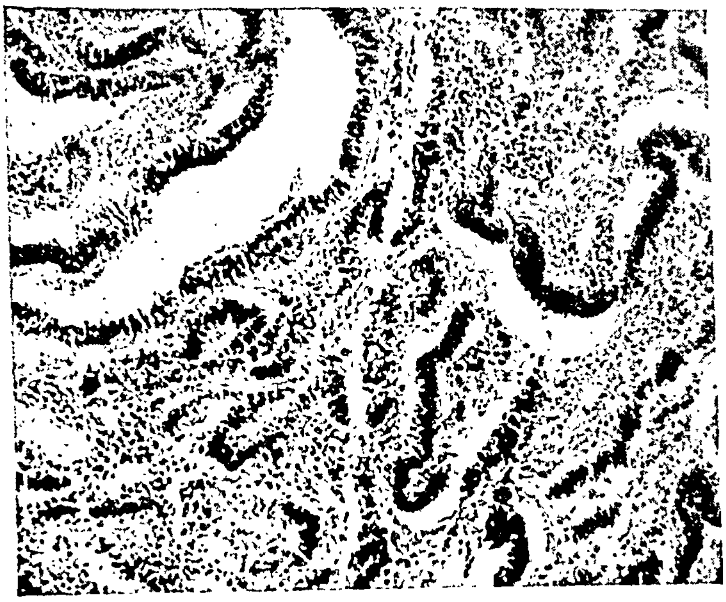

Fig. 1.—Metastatic tumor of broad ligament (X 170).

In spite of the malignant tendency of some carcinoid tumors, several reports show that metastases may lie dormant for several years. Terplan[16] reported a carcinoid of the cecum with metastases in mesenteric glands and liver, in which a biopsy and palliative ileocolostomy was done. The patient died by drowning three and a half years later, and the autopsy showed no progression of the tumor or metastases. Merke[17] reported a case in which a palliative ileocolostomy was done; the patient died of pneumonia and erysipelas five years later, and the autopsy showed no progression of the tumor. Decker[18] reported another case in which carcinoid tumor was found in mesenteric glands, but at autopsy, two and a half years later, no tumor could be found. Mallory[19] reported a most unusual case in which a segment of ileum was resected for carcinoid, with known mesenteric metastases left behind. The patient died 20 years later of pneumonia, and the autopsy showed no further extension of the tumor. Horn's[8] patient with carcinoid of the rectum with extensive metastases lived 17 months, but in this case death was due to metastatic disease.

Another unusual feature we observed in studying the literature was the relatively high incidence of these tumors on the anterior rectal wall, 5 to 10 cm. from the anal margin. In our case the lesion was typically situated on the anterior wall, about 6 to 8 cm. from the anal margin. Of the 72 cases reported in the literature, 22 were of lesions located on the rectal wall. In 14 (an incidence of 64% if the same ratio holds for all of the other cases) the primary tumor was located on the anterior rectal wall, in 3 on the posterior wall, and in 2 on the lateral wall. In two cases the lesion was anular and in one case it was diffuse. In the remaining 50 cases the site was not specified.

REPORT OF A CASE

Mrs. M. T., a 26-year-old white woman, was first admitted to Burge Hospital Oct. 18, 1950, complaining of dyspareunia and a tumor of the left ovary. She stated that the tumor was first found on postpartum examination, in September, 1946, after the birth of her first baby, and that no treatment was advised. She was first seen by one of us (R. N. W.) in October, 1947; she had a normal pregnancy, but the tumor of the pelvis was not noted at the time. She had a normal delivery in April, 1948. On June 23, pelvic examination revealed what was thought to be a prolapsed left ovary. She was examined fairly frequently after this, and in October, 1948, the ovary was thought to be larger. In September, 1949, she again returned, complaining of

low backache and rectal bleeding. An examination at this time revealed the same firm mass in the region of the left ovary, but at this time it was definitely thought to be a tumor in the broad ligament. She was seen in consultation by one of us (C. H. E.); and the diagnosis of an intraligamentary solid tumor was confirmed. A sigmoidoscopic examination disclosed nothing essentially abnormal except for bleeding hemorrhoids. The patient was advised to have the tumor removed at this time, but she declined to do so and she was not seen again until September, 1950, when she returned complaining of dyspareunia, low backache, and rectal bleeding and requested surgery.

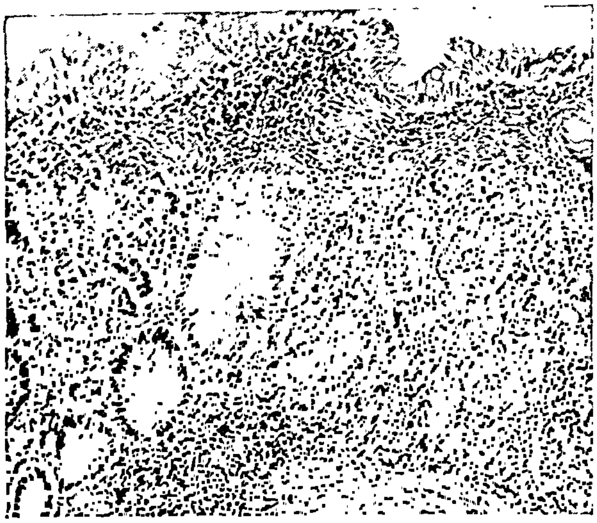

Fig. 3.—Primary rectal carcinoid (× 95).

Her physical examination disclosed nothing abnormal except in the rectum and pelvis. Pelvic examination revealed a parous introitus with fairly good support. The cervix was lacerated bilaterally and mildly eroded, and the uterus was anterior and normal. The right adnexa was normal; but on the left a firm and tender mass, the size of an English walnut, was found deep in the broad ligament just to the left of the cervix. The ovary was palpable anterior to this mass. Rectal examination revealed moderate internal and external hemorrhoids, which bled from the trauma of the anoscope. Laboratory findings were all within normal limits, and the Kahn reaction was negative.

On Oct. 19, pelvic laparotomy was performed. A tumor, approximately 4 by 4 by 5 cm., was found at base of left broad ligament. The peritoneum over the tumor was incised, and the nodule was shelled out easily. Hemostasis was secured and the peritoneum closed. The remainder of the abdomen was explored and found to be entirely normal. The appendix was removed, and the abdomen was closed in the usual manner. The postoperative course was uneventful.

The tumor nodule was studied by one of us (E. B. H.) and thought to be of unusual origin and probably of low-grade malignancy. Dr. Lauren Ackerman (Washington University School of Medicine, St. Louis), who studied the microscopic preparations, felt the tumor was of low-grade malignancy and probably metastatic from the large bowel. Sections of the tumor were sent to several other national authorities, most of whom agreed that it was of low-grade malignancy. Because of its location in the broad ligament, one authority felt it arose from remnants of the wolffian duct; another suggested its origin from the müllerian duct; and another thought it to be a granulosa cell tumor of the ovary. Still another thought it to be a benign tumor arising from remnants of the müllerian duct. On Dr. Ackerman's suggestion a thorough examination was made, which revealed a small tumor on the anterior rectal wall 6 by 8 cm. above the anal margin. A biopsy of this nodule was interpreted as adenocarcinoma.

On Dec. 2, an abdominoperineal resection was done; a portion of the left hypogastric vessels and some of the remaining scar tissue, where the metastasis had previously been removed, were excised. The patient had an uneventful convalescence following this last procedure. The pathologist found the primary tumor to be essentially submucosal, with some muscle infiltration but confined to the bowel wall. In the adjacent lymph nodes and tissue removed from the pelvic wall he found no tumor cells. The final diagnosis was carcinoid of the rectum with retroperitoneal metastasis. Because tumor tissue might have been left on the left pelvic wall, the patient was given a course of roentgen therapy; she was discharged in good condition. During the period Jan. 3 to Feb. 1, 1951, a total of 2,200 r (air) was delivered to each of four anterior and posterior pelvic ports, measuring 10 by 12 cm. each, with the following factors: 250 kv., Thoraeus II filter, and half-value layer of 2.32 mm. copper.

Pathological study of the metastatic tumor revealed it to be firm, 4 by 4 by 5 cm., and well circumscribed, with a slightly bosselated surface. The cut surface revealed a slightly bulging homogenous pale yellowish pink surface with small focal hemorrhages. Microscopic sections showed it to be composed of numerous strands and cords of regular low columnar and cuboidal cells with uniform even-staining nuclei. In most areas the strands were made up of double rows of cells with characteristic festooning as described by Stout (fig. 1).

The second specimen consisted of sigmoid and rectum 30 cm. in length and several small pieces of fibrous tissue. The surface of the colon, rectum, and anal skin all appeared normal, and a careful search of the mesentery failed to reveal any enlarged lymph nodes. When the specimen was opened, the mucous membrane appeared normal except for a 1 by 1 by 1.5 cm. firm elevated nodule on the anterior wall of the rectum 8 cm. above the anal orifice, with no gross evidence of ulceration. The cut surface showed the same firm homogenous white tissue as noted in the metastatic tissue and apparently was limited to the submucosa. The gross appearance is shown in figure 2. Microscopically the tumor was situated in the submucosal layer, pushing the epithelium upward and thinning it out in its center and in small areas producing ulceration. The base of the tumor invaded the muscle superficially but did not extend through the wall. The same cell pattern and architecture as observed in the metastatic tumor were noted. Sections of the rectal tumor are shown in figures 3 and 4.

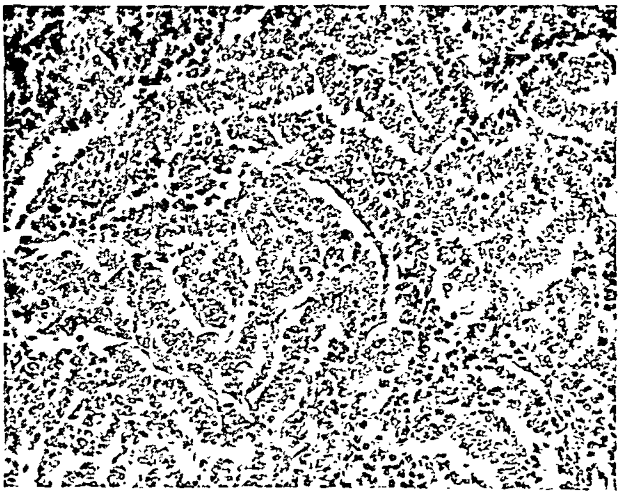

Fig. 4.—Primary rectal carcinoid (× 125).

COMMENT

The pathological changes of rectal carcinoids have been thoroughly studied and adequately described. The carcinoids are characteristically small, firm, hemispherical submucosal nodules situated frequently on the anterior rectal wall 3 to 10 cm. above the anus (table 1). Although Rigdon[20] reported a case in which the entire rectum was covered with small nodules, Pearson and

---

[20] Rigdon, R. H., and Fletcher, D. E.: Multiple Argentaffin Tumors (Carcinoids) of the Rectum, Am. J. Surg. 71:822-824, 1946.

Fitzgerald[10] reported a large annular lesion, and Koch[21] reported a similar constricting lesion, the primary tumor is usually small and single. The benignity of metastases in some instances is exemplified in Horn's patient, with 17 months' survival in the face of extensive spread, and in our own patient, with metastasis of four years' duration and no evidence of spread to other organs or nodes.

All authorities are agreed that these tumors arise from the Kultschitzky (basigranular) cells at the base of the crypts of Lieberkühn. Stout refined this further by suggesting their origin from the pre-enterochrome cells of Erspamer, thereby explaining the absence of argentaffin granules in most of these tumors. Erspamer divided the basigranular (Kultschitzky) cells into four groups, of which the pre-enterochrome cells represent an earlier stage of development and do not show an affinity for

TABLE 1.—*Previously Reported Cases of Carcinoid of the Rectum*

silver stains. All of the reported cases of rectal carcinoids are shown in table 1. Table 2 shows the relative frequency of carcinoids of the rectum as compared to carcinoids occurring in other unusual locations. Most of the patients described were older than our patient; all the patients with malignant carcinoids were older.

Most authors [22] consider rectal carcinoids, as well as carcinoids in other portions of the bowel, as definitely malignant but slow growing and slow to metastasize. Ackerman [22b] believes the infrequency of metastases in carcinoids of the appendix and rectum is based on the fact that they give rise to symptoms early. In the case of appendiceal carcinoids, the symptoms are obstructive and usually appendectomy is performed before metastases take place. In rectal cases bleeding, tenesmus, diarrhea, and backache are early symptoms. The rectum can be easily and satisfactorily examined, which results in a relatively early diagnosis.

TREATMENT

Most writers have advised conservative management of these tumors.[23] Recently, however, Shepard and coworkers [12] advised a more radical treatment and gave several sound reasons for this. The experience of Stout,[9] Helwig,[23c] and Dukes [23d] would seem to obviate radical surgery if no metastasis can be found and if the local lesions are not too large to be removed easily. It is our opinion, after reviewing the literature and reviewing our case, that these tumors should be suspected by their gross appearance and should be treated conservatively if at all feasible. Ariel [24] and Klemperer [25] suggested that radiation may be effective, and Ariel [21] reported one case of carcinoid of the small bowel treated by surgical excision; however, the patient returned two months later with an abdominal mass at the operative site. This mass was irradiated; it responded well, and the patient was well two and a half years later. Ariel suggested, on the basis of this case, that carcinoids may be radiosensitive. Since some patients have lived for years with stationary metastases, it is difficult to evaluate a reaction of this type. It will be interesting, however, to follow our own case to note whether or not further metastases appear.

TABLE 2.—*Unusual Locations of Carcinoids**

SUMMARY

An unusual and uncommon case of a rectal carcinoid metastatic to the broad ligament is reported, which caused considerable speculation and concern in the identification of the first tumor nodule removed. It is our belief that this is the first reported case of malignant rectal carcinoid with known metastasis of four years' duration without spread to other organs. It is one of seven reported cases of malignant carcinoids of the rectum, and the patient in the case reported here is the youngest with proved metastasis.

It is pointed out that even the malignant carcinoids, both of the rectum and other locations, may at times have a remarkably chronic course. The frequency (64%) with which rectal carcinoids appear on the anterior wall of the rectum is mentioned. We believe, after reviewing the literature, that a rectal carcinoid should be suspected when a small tumor of the rectum is found in which the mucous membrane appears intact over the surface and that such tumors should be treated by local excision unless they are diffuse (as in Rigdon's case) or are infiltrating annular lesions (as in Pearson and Fitzgerald's case) or metastatic spread is suspected.

ADDENDUM

At the time of the last examination of this patient on May 20, 1952, 18 months after the abdominoperineal resection, she was well and apparently free of recurrent disease.

Yellow Fever.—Yellow fever, like typhus, is not dead in spite of all of the conquests and conquerors of this disease, nor is it likely to die out so long as the tropical and subtropical forests maintain their mammalian hosts and insect vectors. Jungle yellow fever remains as a potential source of virus for undoing the conquest of urban yellow fever, wherever Aëdes aegypti is permitted to continue, as witness the 1928-29 outbreak in Rio de Janeiro. . . . In South America, only Chile and Uruguay are free from this disease. . . . A tragic occurrence early in 1951 was an outbreak of jungle yellow fever with over 2,000 cases and several hundreds of deaths, among the newly arrived settlers in the State of Goiaz, Brazil. This area had suffered an outbreak in 1945, at which time extensive vaccination was carried out in the then relatively small population. During the past six years, however, an important agricultural development has brought in large numbers of nonimmunes from Northeast Brazil. . . . Ironically enough, these newcomers came from the previously highly endemic region of aegypti-transmitted yellow fever of Northeast Brazil, where there is no jungle yellow fever. It was here that the Rockefeller Foundation initiated its campaign in Brazil against aegypti-transmitted yellow fever in 1923, with the resultant development of this nonimmune susceptible population. . . . As the years pass and jungle yellow fever continues to be jungle yellow fever, without invasion of the cities, the potential threat seems unimportant to many who do not realize the tremendous effort which has gone, and is going, into the eradication of Aëdes aegypti in all of the towns and cities in close contact with the infected forests.—F. L. Soper, M.D., The Elephant Never Forgets, *American Journal of Tropical Medicine and Hygiene,* May, 1952.

CLINICAL NOTES

LIVER NECROSIS AND DEATH FOLLOWING HEPATIC ARTERY LIGATION

David Rosenbaum, M.D.
and
Herbert L. Egbert, M.D., Indianapolis

Recent reports, first by Rienhoff[1] and later by Berman,[2] have indicated that patients with cirrhosis complicated by esophageal varices and ascites may benefit from ligation of the hepatic artery. It has been commonly assumed previously that viability of the liver was dependent on adequate blood supply through the hepatic artery and that ligation of this vessel would result in liver necrosis and death. Markowitz, Rappaport, and Scott[3] reported that in dogs liver necrosis and death following such an operation could be avoided, in most cases, by administration of penicillin, indicating that the necrosis was probably the result of infection from the anaerobic bacteria normally present in the liver of dogs. Grindlay, Mann, and Bollman[4] recently suggested the possibility that in those animals that survived there had not been complete stoppage of the blood supply to the liver through the ligated artery or that collateral channels had been established. These recent reports of successful ligation of the hepatic artery in patients with cirrhosis suggest that in cirrhosis the blood supply to the liver has been so altered that such ligation does not result in damage to the liver and that the function of the liver may even be improved. We have recently observed a case of cirrhosis in which ligation of the hepatic artery was not tolerated and resulted in liver failure and death. This case indicates that ligation of the hepatic artery is not innocuous in all cases of cirrhosis.

REPORT OF A CASE

The patient was a white man, 40 years old, who was admitted to this hospital twice because of massive upper gastrointestinal hemorrhage. He had had an attack of jaundice at the age of 26 and a questionable attack at 34. He admitted excessive use of alcohol for several years, and for the past two or three years, he had had symptoms of indigestion, vertigo, syncope, and edema of the legs.

First Hospitalization.—The patient was first admitted to the hospital on July 12, 1950, after having passed blood in his stools and having vomited a large amount of bright red blood during the preceding four days. Physical examination revealed a soft systolic murmur heard over the entire precordium, several spider nevi over the neck and shoulders, enlargement of the liver 2 cm. below the costal margin, and a small amount of ascites. Laboratory tests made between July 12 and July 20 showed the following results: red blood cell count 2,100,000; gastric analysis showed 20 degrees of free hydrochloric acid; the blood serum contained 1.2 mg. of bilirubin, 5.7 gm. of protein, and 2.8 gm. of albumin per 100 cc.; reaction to the cephalin-cholesterol flocculation test was 2+, and to the thymol flocculation test was negative; a thymol turbidity test showed 5 units, and a zinc turbidity test, 25 units. Tests made between Aug. 20 and Aug. 30 showed the following results: the blood serum contained 0.8 mg. of bilirubin, 7.9 gm. of protein and 4.9 gm. of albumin per 100 cc.; reaction to the cephalin-cholesterol flocculation test was 3+ and to the thymol flocculation test was negative; a thymol turbidity test showed 2 units; and the sulfobromophthalein (bromosulfalein®) sodium retention in the blood was 24%. An x-ray examination revealed a large ulcer crater or pseudodiverticulum of the first portion of the duodenum. Esophagoscopic examination showed large thin-walled varices in the lower esophagus, with no evidence of recent hemorrhage.

The patient's treatment consisted of transfusions, ulcer management, and supportive therapy for cirrhosis. He had no further recurrence of bleeding and was discharged from the hospital on Sept. 5, 1950. He was seen six weeks later, at which time he complained only of mild epigastric discomfort and had had no further episodes of bleeding.

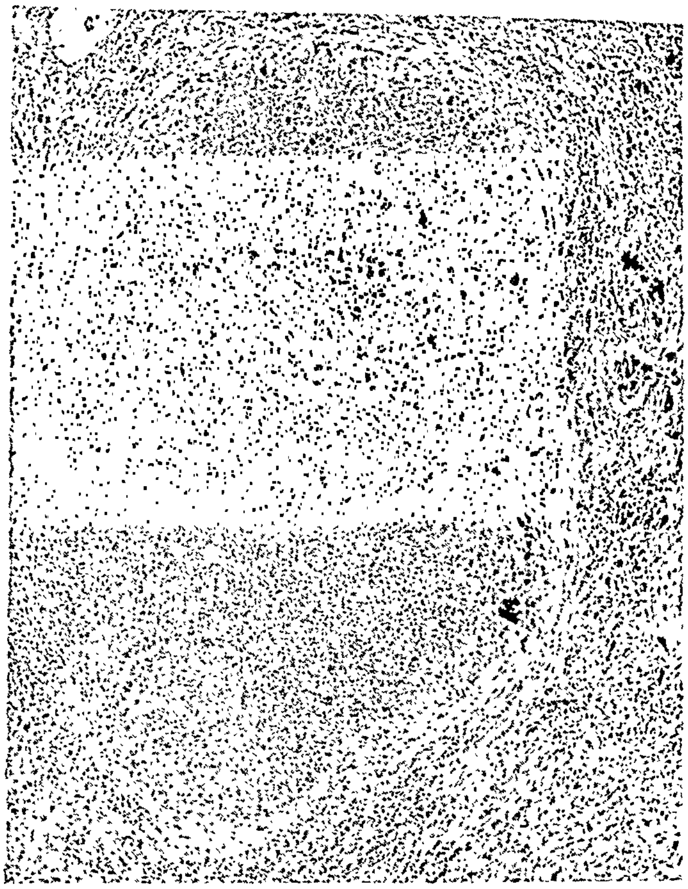

Fig. 1.—Photomicrograph of liver tissue at necropsy showing hemorrhagic infarction of cirrhotic lobule.

Second Hospitalization.—The patient was readmitted to the hospital on March 13, 1951, because of epigastric distress and hematemesis. He stated that he had had no form of treatment after his discharge from the hospital and had had frequent burning pain in the upper abdomen. He had an episode of severe bleeding in December, 1950, and again just prior to admission. Physical examination revealed spider nevi, enlargement of the liver 2 to 3 cm. below the costal margin, moderate epigastric tenderness, and gross evidence of anemia. The patient's blood pressure was 125/85 mm. Hg. An x-ray examination made several days after admission revealed a high degree of spasticity and some deformity of the duodenum. Results of laboratory tests made at this time were as follows: red blood cell count 2,200,000 to 4,000,000; total nonprotein nitrogen content of blood 54 mg. per 100 cc.; prothrombin 58 to 96% of normal; blood serum contained 1.6 mg. of bilirubin, 6.8 gm. of protein, and 3 gm. of albumin per 100 cc.; reaction to the cephalin-cholesterol flocculation test was 4+ and to the thymol flocculation test was

[4] Grindlay, J. H.; Mann, F. C., and Bollman, J. L.: Effect of Occlusion of the Arterial Blood Supply to the Normal Liver, A. M. A. Arch. Surg. 62: 806-811 (June) 1951.

negative; a zinc turbidity test showed 24 units; reaction to the colloidal red test was 4+, to the galactose tolerance test was normal, and to a serologic test for syphilis was negative. Esophagoscopic examination again revealed the presence of large, thin-walled varices in the lower esophagus, which had undergone little change since the previous examination.

Because of the recurrent hemorrhages, it was felt that the patient should have surgical treatment, although it had not been determined whether the bleeding was occurring from the varices or the duodenal ulcer. The operation was done April 16, 1951, with the patient under intratracheal ether anesthesia, which lasted four hours; 2,500 cc. of blood was given during the operation. Exploration revealed considerable nodular cirrhosis and some enlargement of the liver. The spleen was about three times normal size and had no unusual adhesions to the diaphragm. There were some moderately dilated veins about the upper stomach. A great many adhesions were present about the free edge of the lesser omentum, making dissection of this area difficult and bloody. A large, posterior, penetrating duodenal ulcer, which was not actively bleeding, was present about 2 cm. from the pylorus. Measurements of portal pressure were taken in a large gastroepiploic vein, using the second lumbar vertebra as a base line; the pressure thus obtained was 430 mm. of water. Temporary occlusion of the portal vein resulted in no change in this pressure; with temporary occlusion of the hepatic artery, a fall of 10 to 20 mm. of water was observed.

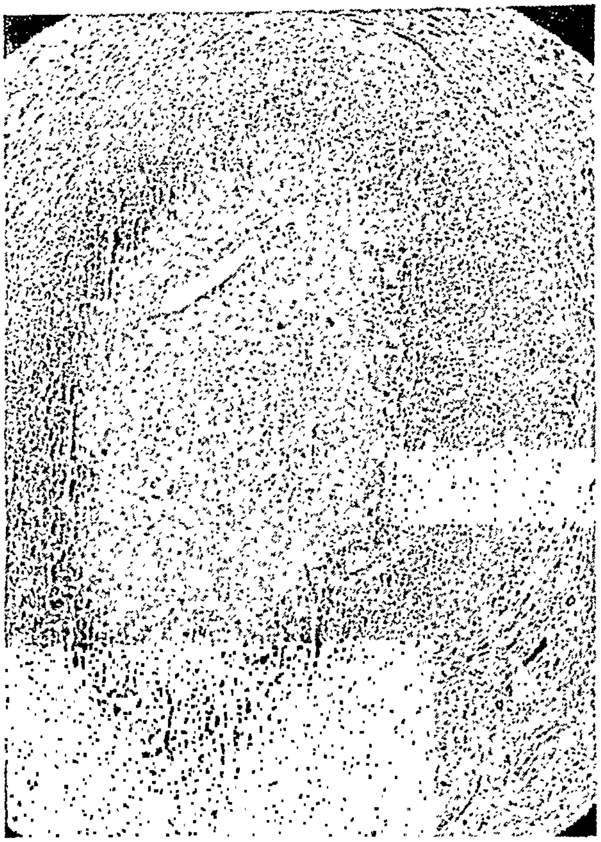

Fig. 2.—Photomicrograph of liver tissue at necropsy showing ischemic infarction of cirrhotic lobule.

It was felt that the source of the bleeding had not been determined with certainty and that prevention of further bleeding from both the duodenal ulcer and the varices should be provided. Accordingly, vagotomy and partial gastric resection were done, and, in addition, the hepatic artery was ligated just proximal to a large gastroduodenal branch. During the operation the patient's condition was fair, although his blood pressure for a long period of time was about 80/60 mm. Hg. The patient's tendency to bleed seemed to increase, and considerbale oozing was encountered, even during wound closure.

The immediate postoperative course was satisfactory. On the evening following the operation the patient's blood pressure fell, and there was considerable oozing of blood from the wound. He was given supportive treatment, with further blood transfusion, and his blood pressure rose to a normal level. On the day after the operation, he became progressively drowsier and more lethargic. In spite of administration of large amounts of vitamin K, the prothrombin level dropped to 23% of normal. The red blood cell count at this time was 4,200,000, and the serum bilirubin content was 9.2 mg. per 100 cc. The patient was treated with plasma, whole blood, vitamin K, human serum albumin, cortical extract, and cortisone, but his course was progressively downhill, with increasing jaundice and lethargy and rising temperature. He died on the second postoperative day.

Necropsy.—Necropsy was performed eight hours after death. The skin and scleras were highly jaundiced. No evidence of hemorrhage was found in the abdominal wound. There was almost 400 cc. of bloody fluid in the peritoneal cavity, and a fibrinous exudate was present over the surface of the liver and greater omentum. The lungs showed beginning bronchopneumonia and minimal edema. No definite esophageal varices could be found. The spleen was enlarged, weighing 450 gm., and appeared to be congested. The liver was enlarged, weighing 2,360 gm., and was extremely cirrhotic, with nodules of varying sizes over the surface and throughout the cut sections. Gross hemorrhage was apparent in most of these regenerated cirrhotic nodules, although occasional lobules presented a yellowish, caseous appearance, with peripheral zones of hemorrhagic discoloration. The portal vein was normal in appearance, and its lumen contained no thrombotic material. The hepatic artery was completely ligated immediately proximal to the gastroduodenal branch, and had no thrombosis, either distal to or proximal to the ligature.

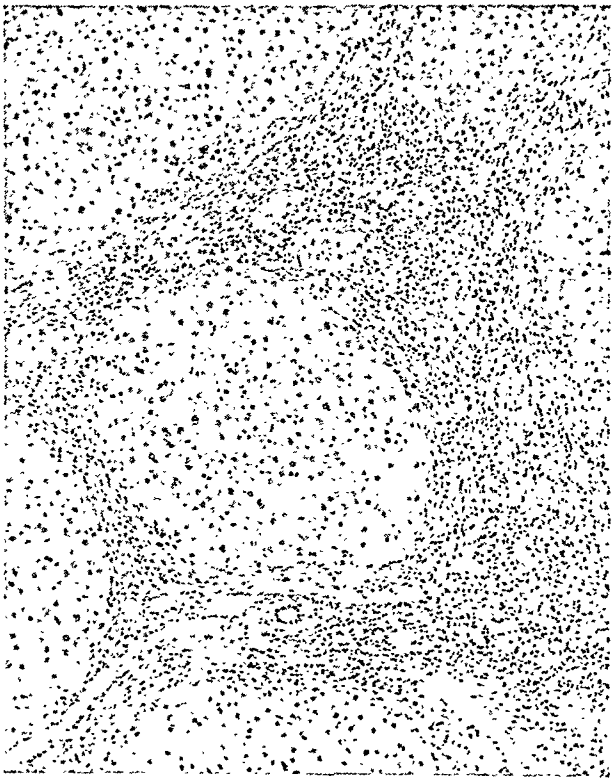

Fig. 3.—Photomicrograph of section of liver taken for biopsy during the operation for ligation of the hepatic artery showing typical portal cirrhosis with viable hepatic parenchyma.

Important microscopic changes were observed in the liver. The underlying condition was typical portal cirrhosis. The architecture was completely disrupted by broad and narrow bands of fibrous connective tissue, in which there were numerous lymphocytes and proliferated bile ducts. These interlacing bands enclosed and rather sharply demarcated lobules of regenerated hepatic parenchyma of varying sizes. In addition, recent superimposed changes of two general types were observed in the regenerated lobules. Most of the lobules were hemorrhagic, with

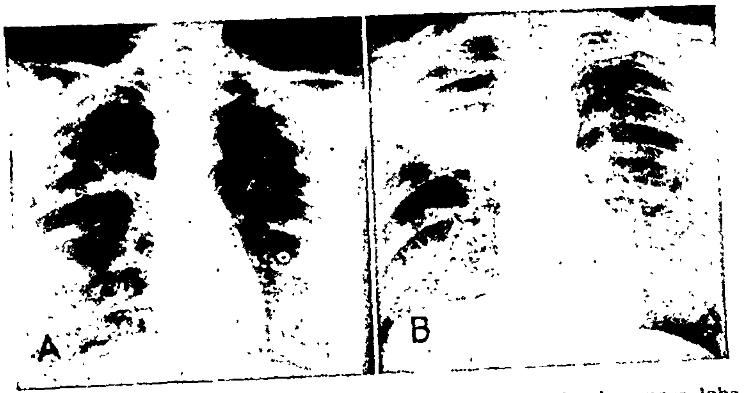
EXACERBATION OF TUBERCULOSIS DURING TREATMENT WITH CORTISONE

Eugene F. Traut, M.D., Oak Park, Ill.
and
Jerome Ellman, M.D., Chicago

Observations of the unfavorable effects of corticotropin (ACTH) and cortisone on tuberculosis are multiplying. Guinea pigs and rats taking these drugs have succumbed to doses of tubercle bacilli found nonlethal in controls.[1] Pulmonary tuberculosis in humans has also disseminated during steroid administration.[2]

REPORT OF A CASE

S. M., a 37-year-old Negro woman, was seen in the arthritis clinic of Cook County Hospital in July, 1950, because of rheumatoid arthritis of five years' duration. The arthritis, involving all four extremities, was so severe that she was barely able to walk with help. The laboratory tests revealed the presence of hypochromic anemia and an accelerated erythrocyte sedimentation rate, findings commonly encountered in severe rheumatoid arthritis. She had no symptoms referable to the respiratory tract nor abnormal physical findings in the lungs. During case-finding studies she had previously had x-ray studies of her lungs. During two admissions to another hospital for treatment of the arthritis, routine roentgenograms had been made. She had never been told that these indicated pulmonary disease. She had never suspected any lung abnormality until, following discharge from Cook County Hospital in June, 1950, a visiting nurse had advised her to have x-ray studies of her lungs each six months. No reason for this advice was advanced.



A, roentgenogram of the chest showing infiltration in the upper lobe of the right lung before cortisone therapy in May, 1950. *B*, roentgenogram showing marked spread of the lesion during cortisone therapy in January, 1951.

On admission to Cook County Hospital in September, 1950, she was give cortisone (cortone® [Merck]) orally in doses of 300 mg. the first day, 200 mg. the second day, and 100 mg. daily thereafter. Within 24 hours there was a marked decrease in all the symptoms and signs of arthritis. Her appetite, strength and spirits rose correspondingly. Her weight increased 2 lb. (0.9 kg.) within four weeks. There was no demonstrable edema.

Symptoms of a "cold" developed in the 12th week of cortisone therapy. Cough, fever, and expectoration persisted. The patient complained of night sweats. Tubercle bacilli were found in the sputum, and marked extension of the tuberculosis was demonstrated roentgenologically (figure).

Administration of cortisone was discontinued, and the arthritis was temporarily much worse. Subsequently and concurrently with the bed rest enforced because of the tuberculosis, remission of the arthritis has occurred. The roentgenologic evidences of tuberculosis remain the same. The temperature is normal, and there is no cough nor production of sputum.

I have other patients with arrested pulmonary tuberculosis who are receiving cortisone for crippling rheumatoid arthritis without any apparent increase in their pulmonary infection.

CONCLUSION

Patients who are to receive corticotropin (ACTH) or cortisone should be examined for tuberculosis, including by roentgenologic studies. Any findings that suggest the presence of tuberculosis should be carefully and frequently reviewed for possible activation during treatment with corticotropin or cortisone. The presence of pulmonary tuberculosis may contraindicate the use of corticotropin or cortisone.

TESTICULAR ANDROGEN DEFICIENCY AND SEMEN VOLUME

E. Perry McCullagh, M.D.
and
C. A. Schaffenburg, M.D., Cleveland

The assessment of androgenic activity in male subjects by simple and easily accessible methods is highly desirable. Tests such as the determination of 17-ketosteroids and urinary gonadotropins are not readily available to the general practitioner. Also, the proper clinical evaluation of the secondary sex characteristics (e. g., frontotemporal recession of the hairline, the beard, and pubic and axillary hair) requires familiarity with these signs, and they have the disadvantage of not relating directly to the levels of androgens circulating at the time of examination. We wish, therefore, to call attention to the use of semen volume measurements as an index of androgenic function.

There are, as Huggins[1] pointed out, two different types of male secondary sex characteristics: the self-maintaining (such as beard and voice pitch), which once developed will not atrophy in the absence of androgen, and those depending strictly on a constant presence of this hormone for the maintenance of their anatomic and functional integrity. In the latter category are the sex accessories, such as prostate and seminal vesicles. From this it follows that any serious decrease in the amount of circulating androgen will be reflected in the sex accessories and, therefore, in semen.

Semen is composed of two parts: (1) the spermatozoa, produced by the seminiferous tubules, and (2) the plasma, produced by the sex accessories where prostate and seminal vesicles contribute the largest portion. When there is failure of the seminiferous tubules (or

---

[1] Huggins, C.: Prostatic Secretion, Harvey Lect. (1946-1947) **42**: 148, 1947.

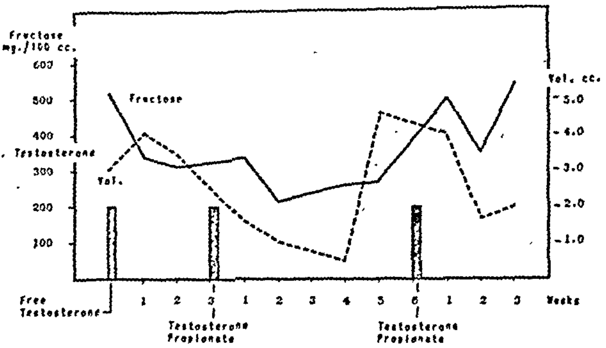
mechanical obstruction distad to them) there may be oligospermia or even azoospermia. However, if Leydig cell function is preserved, as is often the case, semen volume is normal, since the sex accessories are receiving an adequate androgen supply.

There are in plasma a number of chemical substances, characteristic of different portions of the sex accessories, the concentration of which depends on the amount of circulating androgen. In man, the enzyme "acid" phosphatase is elaborated in the prostate [2] and a sugar, fructose, in the seminal vesicles. Both of these substances have been variously utilized as an index of androgenic function.[3] Fructose concentration parallels semen volume up to amounts of 4 to 5 cc. Above this its concentration decreases.[3c] In the accompanying table we have plotted the average fructose concentration in milligrams per 100 cc. of semen as related to the volume of several specimens obtained from patients with hypogonadism treated with testosterone preparations. It will be noted that fructose concentrations increase proportionately with semen volume although the range of variation is great. In some men fructose concentration shows an inverse relationship to semen volume. This is exemplified in the accompanying figure.

Recently Landau and Loughead [4] utilized fructose measurements as an index of androgen activity in eunuchoid or normal persons. In our hands fructose determinations have proved to be no more valid indexes of androgenicity than the semen volume alone. The reasons for this are that the normal individual variations are large (from about 200 mg. per 100 cc. to 800 mg. per 100 cc.) and that there are no significant changes in fructose concentration in the absence of changes in semen volume. In severe, untreated eunuchoidism, the subject is incapable of erection or ejaculation or the semen volume is extremely low (0.1 cc. or less). When androgen is administered the volume gradually increases until it reaches a normal level. Semen specimens should be obtained after four days of continence; in these conditions normal semen volumes vary from 2 to 7 cc. Volumes of more than 3 cc. on repeated examinations and especially volumes over 5 cc. can be considered good evidence that there is no deficiency of circulating androgen. Amounts of less than 2 cc. on repeated occasions raise the suspicion of androgen deficiency. If this has developed in a fully matured person, other signs may not be evident. A more thorough endocrine investigation is then warranted.

Relationship of Fructose Concentration to Semen Volume in Azoospermic, Eunuchoid Patients Treated with Testosterone

No. of Patients	No. of Specimens	Vol. (Cc.)	Fructose Concentration, Mg. per 100 Cc.	Range
6	23	1.0 or less	192	45-560
5	31	1.1-2.0	331.8	170-585
7	21	2.1-3.0	427.1	155-615
6	27	3.1-4.0	431.2	215-655
4	13	4.1-5.0	529.2	270-740



Cryptorchism with eunuchoidism: effect of testosterone propionate therapy on semen volume and semen fructose concentration.

SUMMARY

Attention is called to the fact that in clinical practice the simple procedure of measurement of semen volume may be used to advantage as a screening test for hypogonadism insofar as it relates to testicular androgen production.

RECURRENT NATURE OF ACUTE BENIGN PERICARDITIS

Clyde E. Tomlin, M.D.
R. Bruce Logue, M.D.
and
J. Willis Hurst, M.D., Emory University, Ga.

Despite the extensive literature relating to acute benign pericarditis and the observation of recurrent attacks by various writers,[1] the high incidence and the frequency of recurrences in this illness have not been stressed. It is the purpose of this paper to emphasize this point by presenting a detailed report of one patient and summarized data for eight patients, in whom such episodes of acute benign pericarditis occurred (see the accompanying table). The following case, in which the largest number of recurrences was observed, is presented as an example of this group.

From the Department of Cardiology, Emory University School of Medicine.

REPORT OF A CASE

F. J. G., a 27-year-old white woman, a registered nurse, was admitted to the hospital on July 21, 1950, with the chief complaint of sudden onset of severe substernal and precordial pain, accentuated by inspiration and by lying in the supine position but not increased by swallowing. She had her first attack of such pain at the age of 6 years; 19 subsequent attacks occurred. The longest interval between recurrences was four years. Occasionally respiratory infection preceded an attack. Results of physical examination were normal except for temperature of 100.4 F. The cardiac rhythm was regular. There was no murmur, rub, or gallop rhythm. Examination of the lungs revealed no abnormality. There was no mediastinal crepitation.

The sedimentation rate was 24 mm. per hour (Westergren). The white blood cell count was 10,650 per cubic millimeter, with a normal differential count. Roentgenograms of the gallbladder, gastrointestinal tract, cervical and thoracic spine, and chest were normal. Results of fluoroscopic examination of the chest were normal. The electrocardiogram revealed shortening of the T vector in the frontal plane with isoelectric T waves in V_3 and V_4. The patient had low-grade fever for two days. The pain gradually disappeared, and she was asymptomatic when she was discharged, on the fourth hospital day.

One month later the same symptoms reappeared. Physical examination revealed a faint pericardial friction rub in the fourth anterior intercostal space in the midclavicular line. Her temperature was 99.2 F. An electrocardiogram taken five hours after the onset of the pain revealed marked lowering of the T waves in all leads. The use of narcotics was necessary for the relief of the pain, and she was asymptomatic in six days. The patient was subsequently hospitalized elsewhere on two occasions because of recurrence of the same symptoms.

Summary of Data

Patient	Age, Yr.	Sex	Antecedent Infection	No. of Recurrences	Chill	Character of Pain
J. H.	31	M	Measles 3 weeks prior to first attack	3 (1) 1942 (2) 1948 (3) 1949	....	Severe substernal, radiating to shoulder, lasting 10 days, not relieved by glyceryl trinitrate therapy, aggravated by deep breathing, movement, and walking
H. W.	33	M	Acute sinusitis 10 days prior to first attack	4 (1) 1948 (2) 1948 (3) 1949 (4) 1950	Yes	Epigastric and substernal, stabbing, radiating to neck, arms, fingers, aggravated by movement, swallowing, breathing; patient acutely ill
R. I.	25	M	None	9 between Nov., 1950, and May, 1951	No	Dysphagia, pain radiating from pharynx to left shoulder
F. J. G.	27	F	Occasional infection	19 since age of 6 yr.	No	Sharp, substernal and precordial pain, aggravated by cough, movement, and respiration
M. M. B.	45	F	None	8 between 1945 and 1949	Yes	Intermittent sharp, midsternal pain, radiating to arms; constant dull ache; patient acutely ill; sat upright
W. F. G.	50	M	None	2	Yes	Sudden, severe substernal, nonradiating pain aggravated by respiration, movement, and swallowing; acutely ill; intravenous use of morphine required
Case No. 14 [1b]	25	M	None	History of attack 1 yr. previously	....	Sharp precordial pain, aggravated by inspiration, coughing, and turning
Case No. 15 [1b]	46	M	Upper respiratory infection for 1 mo.	4	No	Pain in left shoulder, anterior chest, neck, increased by movement, cough, and sneezing

* Rourke-Ernstene method.

COMMENT

The symptoms, physical findings, laboratory data, and the electrocardiographic changes have been discussed elsewhere.[2] The pain is usually substernal or precordial, and from the onset the striking characteristic of the pain is its close relationship to inspiration, bodily movements, cough, and sometimes swallowing. Occasionally the patient may be acutely ill and may present the picture of peripheral collapse. Frequent examinations may be necessary for the detection of the pericardial friction rub. Cardiac dilatation is believed by some to occur,[3] but the increase in the cardiac silhouette is more likely due to pericardial effusion, which is probably present in small amounts in most cases.[4] Pleural effusion may at times be noted.

In acute benign pericarditis an injury current due to diffuse subepicardial myocarditis is reflected on the electrocardiogram as concave S-T segment elevation in one or more leads.[1b] It is important to differentiate these changes from the persistent S-T elevation seen occasionally in normal subjects having T vectors of large magnitude, with early forces of repolarization giving rise to S-T elevation. The T waves may be tall and peaked at the onset, but after a short time they are flattened and later may become inverted. The T-wave changes may be

the only electrocardiographic abnormality present. QRS abnormalities do not occur.

Of most importance in the differential diagnosis is myocardial infarction. The early appearance of the pain of pericarditis and the fever and pericardial friction rub without electrocardiographic changes of myocardial infarction help establish the diagnosis of acute benign pericarditis. Tuberculous pericarditis is more often painless, and the onset is usually gradual, associated with antecedent weakness, night sweats, fever, and weight loss. The pericarditis of rheumatic fever is almost always associated with signs of myocarditis, which are not seen in patients with acute benign pericarditis. Nay and Boyer have stressed the importance of coincident joint manifestations and leukocytosis in acute pericarditis due to rheumatic fever.[2b]

in Eight Cases

		Maximum				Electrocardiographic Changes	
Friction Rub	Pulse Rate	Temperature (F)	White Blood Cell Count	Sedimentation Rate	Chest Roentgenographic Observations	*S-T Segment*	*T Wave*
History of rub with 1st attack	70	Low-grade fever for 2 days	......	..	....	Elevated in all leads	Inverted in leads 1, V_5, and V_6
With first attack only	70-100	100.8	11,800	52	Small amount of fluid in costophrenic angles; cardiac silhouette normal	Elevated in leads 1 and 2, depressed in 3	....
Present	100	.....	8,000	15	Cardiac enlargement; infiltration in left base, with fluid	....	....

The cause of acute benign pericarditis remains obscure. In some cases it is possible to elicit a history of preceding infection, usually in the upper respiratory tract.[5] Acute benign pericarditis is sometimes seen in association with atypical pneumonia.[6] Barnes and Burchell stated the belief that occasionally a young adult may have a benign, apparently self-limited form of pericarditis, which may possibly have been due to tuberculosis.[1c] Nathan and Dathe suggested a hypersensitive response to an offending organism as a possible causative factor.[4b] It would seem more likely that the disease is due to a virus infection. If there is an immunologic response on the part of the host, it would appear to be a transitory one, in view of the repeated attacks in some patients.

The present treatment is symptomatic. Bed rest is recommended for one week, with gradual increase in activity over a period of two to three weeks. Various antibiotics,[7] chemotherapeutic agents,[6b] and antihistaminic drugs [8] have been used in the treatment of the disease, but their evaluation is difficult because the natural course of the illness is toward recovery. Taubenhaus and Brams expressed the opinion that the improvement noted in their three patients treated with aureomycin was prompt and impressive enough to warrant its further use.[9] One of our patients received aureomycin for five days during a recurrence, and another received terramycin for seven days. The pain subsided coincidentally with the administration of these antibiotics, but we do not believe that it is possible to attach any significance to this. During one acute attack the patient described above received 50 mg. of corticotropin (ACTH) without any relief of the pain.

Although further study and observation of cases will be needed before definite conclusions can be drawn, it is generally believed that the prognosis for patients with acute benign pericarditis is good and that constrictive pericarditis does not occur. Of a series of 27 patients with acute benign pericarditis described by Levy and Patterson, 23 were reexamined at intervals of 6 months to 16 years following the acute illness.[11] All showed complete recovery without sequelae. Barnes and Burchell followed 14 patients, none of whom has shown residual damage from previous pericarditis.[10] The patient described above, after having experienced 19 attacks of acute benign pericarditis over a period of 19 years, showed no evidence of residual damage at the time of last examination.

SUMMARY

The recurrent nature of acute benign pericarditis is emphasized. A report of a case and summarized data in a series of eight cases of the disease, in which the number of recurrences ranged from 2 to 19, are presented. The clinical aspects of the disease are briefly reviewed.

SEGMENTAL FORCEPS

Richard H. Overholt, M.D., Boston

A special forceps has been designed for use on the uncovered surface and edge of pulmonary segments. The new segmental forceps has a narrow bite with fine-tooth edges. The shafts are flared above the tip, which automatically throws the loop of thread down over its end and into lung tissue as the knot is tightened. The possibility of including the tip of the instrument in the ligature is eliminated (fig. 1).

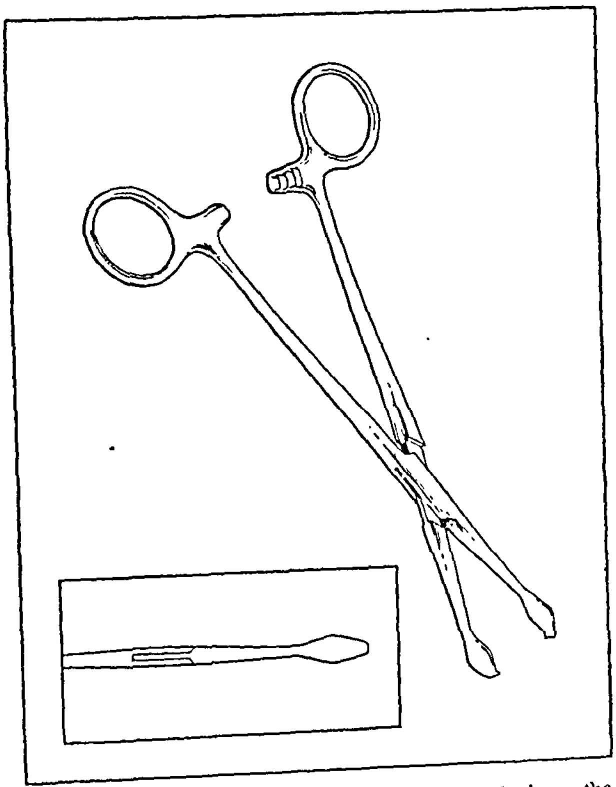

Fig. 1.—Segmental forceps, showing the shafts flared above the tips.

In sealing air leaks on segmental surfaces devoid of pleura, there is a need to grasp small amounts of tissue about the point of escape of air and to set a circumferential ligature beyond the point of the instrument (fig. 2*B*). The lung must be expanded to prove air tightness, and leaks should be sealed with segments in their normal state of inflation. If a leak is present, needle suturing produces more leaks. Ordinary hemostats, either straight or curved, gather up too much tissue, thus tending to reduce the volume of the segment and deform its surface.

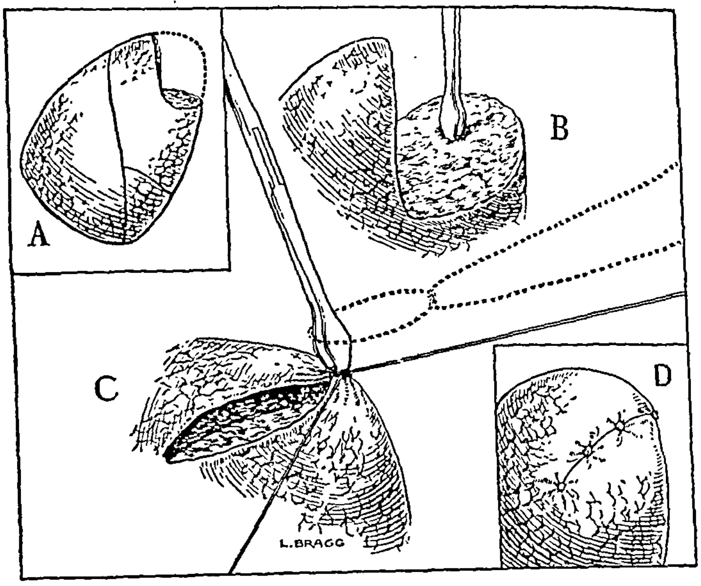

Fig. 2.—Uses of segmental forceps. *A*, apical segments after enucleation. *B*, forceps grasping small amounts of tissue to seal air leaks. *C*, segments grasped by forceps, showing ligature in position. *D*, segments anchored with ligatures.

The segmental forceps has a second use; namely, the approximation of the edges of segments or lobes. Whenever possible, it is desirable to bring two denuded segmental surfaces together; for example, after enucleation of an apical segment (fig. 2*A*), the surfaces of the anterior and posterior segments can be brought together by fastening edges at three or four points. This should be done with the segments fully inflated (fig. 2*C* and *D*).

It is also desirable to anchor a single remaining segment of one lobe to the adjacent intact lobe. This can be done by a slight shift in its position with abutment of the denuded surface of the segment against the interlobar surface of the intact lobe. This prevents rotation of the single segment, aids in sealing small air leaks, and minimizes the formation of adhesions between lung and chest wall. The fastening of segment to lobe must be done when they are inflated. The segmental forceps grasps the edge of each at three or four sites, and the tissue included in each bite is anchored with a ligature, which slips over the end of the instrument.

1101 Beacon St. (Brookline, Mass.).

The forceps was manufactured by Codman & Shurtleff, Inc., 104 Brookline Ave., Boston.

From the Department of Surgery, Tufts College Medical School, Boston. Member of the staff of New England Deaconess Hospital and New England Center Hospital, Boston.

Brain Growth.—The human skull yields to the normal outward push of the growing brain during infancy and earliest childhood. At this period, therefore, brain injury or brain destruction results in overlying cranial smallness. The rate of growth is astonishingly rapid at first for the brain increases from an average weight of 300 gm. at birth to 500 gm. at six months. At two years the weight may normally reach 900 gm., and at puberty 1,200 gm., after which there is ordinarily an increase of no more than 100 gm.—Wilder Penfield, M.D., Cranial Clues to Intracranial Abnormality, *The American Journal of Roentgenology*, April, 1952.

THROMBOCYTOPENIC PURPURA INDUCED BY SULFISOXAZOLE (GANTRISIN®) THERAPY

REPORT OF A CASE CONTROLLED BY PLATELET TRANSFUSION

Jacob Geiger, M.D., New York

Sulfisoxazole (gantrisin®), 3,4-dimethyl-5-sulfanilamido-isoxazole, introduced in 1946, is widely used in treatment of bacterial infections, especially those of the urinary tract. The drug is said to be one of the safest of the sulfonamides. It is described by the manufacturer as a "single drug—not a mixture of several sulfonamides—so that there is less likelihood of sensitization" and as "having greater solubility and higher blood-levels." As is the case with other members of the sulfonamide group, however, reports of toxic reactions have appeared in the literature. Aside from reports of nausea, vomiting, headache, fever, and dermatitis, a number of instances of toxic effects on the bone marrow have been reported. Haunz, Cardy, and Graham [1] collected eight cases of leukopenia following the use of gantrisin,® and recently Hagerman and Franzblau [2] added another. A careful search of the literature for cases of hemorrhagic manifestations of toxicity has yielded one report [3]—that of a case of petechial hemorrhages following the administration of gantrisin,® 75.5 gm. given over a period of 12 days. In this instance there was moderate leukopenia but no thrombocytopenia. The present case is of interest because of the occurrence of toxic thrombocytopenia with its sequelae and the dramatic response following cessation of treatment with the drug and one transfusion of blood platelets.

† On Dec. 5, at 5 p.m., a transfusion of blood platelet concentrate (450 billion platelets) was given.

REPORT OF A CASE

P. C., a 69-year-old man, was admitted to the hospital on Nov. 25, 1951, with a history of difficulty in voiding for the past two years. During this period he had received hormone injections. The past history revealed an episode of precordial pain with syncope about 10 years previously but was otherwise irrelevant. Results of the physical examination were normal, except with respect to the prostate, which was firm, irregular and diffusely enlarged. X-ray examination of the lumbar portion of the spine and the pelvis showed no evidence of neoplastic metastasis. The preoperative diagnosis was prostatic obstruction possibly due to carcinoma. On Dec. 3, a bilateral vasectomy and transurethral prostatectomy were performed with the patient under general anesthesia. Histological examination showed a carcinoma of the prostate. The patient reacted well. Medication consisted of the administration of sedatives, when indicated, and gantrisin,® 1 gm. three times daily, given from Nov. 25 to Dec. 4 (a total of 21 gm.). Penicillin had been ordered but was not given because the patient stated he was allergic to it. On the morning of Dec. 4, the first postoperative day, edema and what appeared to be purpuric spots on both ankles and hematuria were noted. Within a few hours, when I saw the patient, the rash had become distinctly purpuric, extending over the lower and upper extremities. There was bleeding from both nostrils and the mouth, with severe hematuria and bloody stools. The diagnosis of toxic thrombocytopenia induced by the use of gantrisin® seemed justifiable, and treatment with the drug was discontinued. Hematological examinations and a sternal bone marrow biopsy were made while the patient was being prepared for transfusion. Five hundred cubic centimeters of whole blood (18 hours old) was administered an hour later. The condition remained unchanged for the next 24 hours. Bladder irrigation yielded large blood clots; bleeding from two areas on the inside of the cheeks and from the nose continued. In the meantime a platelet concentrate was prepared from 5 units of fresh blood.[4] At 5 p. m. on Dec. 5 the patient received a transfusion consisting of approximately 450 billion blood platelets suspended in 300 cc. of isotonic sodium chloride solution. Three hours later the bladder washings were considerably less bloody, yielding only a few small clots. Hematological findings indicated pronounced improvement, and it was the general feeling, both from a clinical and laboratory standpoint, that effective hemostasis had been established and that further hemotherapy was not indicated. On Dec. 7, the urine was grossly clear, the mouth lesions had not bled for two days, and there was gradual fading of the purpuric rash. On Dec. 10 the patient was out of bed. He was discharged on Dec. 12 in good condition.

COMMENT

It is reasonable to assume that the thrombocytopenic purpura was induced by treatment with gantrisin.® Administration of a large number of platelets brought about prompt arrest of bleeding, and cessation of treatment with the drug permitted spontaneous regeneration of the bone marrow. The platelet count did not show an immediate rise, but this was to be expected since the platelets are probably withdrawn from the circulation as fast as they are administered, in the process of restoring a normal blood-clotting mechanism.

SUMMARY

A case of toxic thrombocytopenic purpura induced by treatment with gantrisin® (3,4-dimethyl-5-sulfanilamido-isoxazole) is reported. Recovery occurred with dramatic suddenness after cessation of treatment with the drug and a transfusion of blood platelets.

COUNCIL ON PHARMACY AND CHEMISTRY

REPORT TO THE COUNCIL

Some months ago in a random sampling 50 physicians in California were asked the question, "If a narcotics addict came to you for treatment, what disposition would you make of the case?"

Inasmuch as four of the physicians queried indicated that they would treat the addict, while the others gave varied answers, the Council, believing that physicians in general would appreciate a discussion of the question, has authorized publication of the following statement. This statement has been prepared by the Committee on Drug Addiction and Narcotics of the National Research Council with the assistance of Dr. Harris Isbell, Director, National Institute of Mental Health Addiction Research Center, United States Public Health Service Hospital, Lexington, Kentucky.

R. T. STORMONT, M.D., *Secretary.*

WHAT TO DO WITH A DRUG ADDICT

A recent questionnaire circulated in southern California revealed that many physicians were uncertain as to the proper course to be taken when drug addicts appeared in their offices. This paper has been prepared to provide information on the proper procedure in this situation. It will deal only with addiction to those substances covered by the Harrison Narcotic Act and similar laws, such as the Marihuana Tax Act. Specifically, the drugs concerned are opium and all mixtures containing opium, morphine, heroin, dihydromorphinone (dilaudid®), methyldihydromorphinone (metopon), 3-hydroxy-N-methylmorphinan (dromoran®), codeine, dihydrocodeinone (hycodan®), dihydrohydroxycodeinone (eukodal), meperidine (demerol®), methadone (dolophine,® adanon®), marihuana, and cocaine.

PERTINENT FEDERAL REGULATIONS

All physicians who prescribe and dispense narcotics are furnished by the Bureau of Narcotics, U. S. Treasury Department, with Regulations No. 5 relating to the "dealing in, dispensing and giving away of opium or cocoa leaves, isonipecaine or opiates, or any compound, manufacture, salt, derivative or preparation thereof" and with Pamphlet No. 56, "Prescribing and Dispensing of Narcotics under the Harrison Narcotic Law." All physicians should be familiar with these two publications and, furthermore, should realize that the synthetic narcotics, meperidine, methadone, and dromoran,® have been legally defined as opiates and subjected to the same regulations as are morphine and its derivatives. The most pertinent statement concerning addiction is Article 167 of Regulations No. 5, which reads in part as follows: "An order purporting to be a prescription issued to an addict or habitual user of narcotics not in the course of professional treatment, but for the purpose of providing the user with narcotics sufficient to keep him comfortable by maintaining his customary use, is not a prescription within the meaning and intent of the act; and the person filling such an order, as well as the person issuing it, may be charged with violation of the law."

This regulation is interpreted in Pamphlet No. 56, which reads in part as follows: "The responsibility for the proper prescribing and dispensing of narcotic drugs under the Harrison Narcotic Law rests upon the physician in charge in any given case . . . [and] corresponding responsibility rests upon the druggist who fills the prescription to determine, in good faith, that the prescription was issued in the course of professional practice and not for the purpose of gratifying addiction . . . The good faith of the physician and the bona fides of his treatment in a given case will be established by the facts and circumstances of the case and the consensus of medical opinion with regard thereto, based upon the experience of the medical profession in cases of similar nature. Physicians will be expected to exercise such care in every case where narcotic usage is indicated, that the patient under treatment shall receive no quantity of narcotic drug greater than that sufficient for bona fide medical needs in order that there may be no surplus available for possible diversion by the patient to illicit use . . . Mere addiction alone is not regarded or recognized as an incurable disease. It is well established that the ordinary case of addiction yields to proper treatment and that addicts can remain permanently cured when drug taking is stopped and they are otherwise physically restored to health and strengthened in will power."

Many of the individual states have passed narcotic control laws and the physician must be familiar with the laws and regulations of his particular state as well as with the Federal laws. In general, the physician will be acting in accordance with the consensus of medical opinion with regard to addiction and will be complying with the letter and spirit of the regulations if he follows two principles: (1) Ambulatory treatment of addiction should not be attempted as institutional treatment is always required; (2) Narcotic drugs should never be given to an addict for self-administration.

The reasons for establishing these principles are set forth in a committee report adopted by the House of Delegates of the American Medical Association in 1924. The following are excerpts from this report: "Your committee desires to place on record its firm conviction that any method of treatment for narcotic drug addiction, whether private, institutional, official or governmental, which permits the addicted person to dose himself with the habit-forming narcotic drugs placed in his hands for self-administration, is an unsatisfactory treatment of addiction, begets deception, extends the abuse of habit-forming narcotic drugs and causes an increase in crime . . .

"In the opinion of your committee, the only proper and scientific method of treating narcotic drug addiction is under such conditions of control of both the addict and the drug that any administration of any habit-forming narcotic drug must be by, or under the direct personal authority of the physician with no chance of any distribution of the drug of addiction to others, or opportunity for the same person to procure any of the drug from any source other than from the physician directly responsible for the addict's treatment."

DIAGNOSIS OF ADDICTION

Most frequently, addicts who appear in a physician's office are transients who are unknown to the physician. Such persons are likely to appear when circuses and carnivals are present in a community. Less commonly, addicts may be nontransient persons who are fairly well known to the physician. Frequently, nontransient addicts are neurotic persons or are patients who are known to have been chronic alcoholics. It is not unusual for the nontransient addict to be a physician. In recent years, it has not been unusual in certain areas for an adolescent boy or girl to be brought to the physician by relatives or by representatives of social organizations for advice relative to the treatment of addiction.

Most frequently, the diagnosis of addiction is made at the onset of the interview by the patient's statement that he is addicted to and needs drugs. The addict may attempt to conceal his addiction and may present a glib story of some physical illness; most frequently mentioned are atypical angina pectoris, kidney colic, migraine, or hemorrhoids. Generally, the story culminates with the suggestion that other physicians have found that the only adequate remedy is a prescription for narcotic drugs. Frequently, addicts of this type may appear armed with a formula which they state was given to them by another physician and which they have found very effective for the relief of their alleged symptoms. The formula will usually contain morphine, laudanum, or cocaine. If refused morphine, many addicts will ask for either methadone or meperidine. They will state that these drugs are not opiates but are synthetic drugs and are nonaddicting. All too frequently, uninformed physicians will be taken in by this story and will prescribe the synthetic analgesics. It is not unusual for addicts to attempt to obtain narcotics on the basis of some mild, chronic, nonfatal disease, such as asthma, arthritis, or chronic osteomyelitis, for which narcotics are not usually required or given. They will state that these diseases cause them terrible pain, that physicians in another town have been prescribing narcotics, and that their own physicians are away and they need drugs only until he returns. Occasionally, transient addicts may appear who are suffering with serious physical diseases, such as advanced cardiovascular diseases or emphysema. These cases present particularly difficult problems of treatment since the stress of abrupt withdrawal might prove fatal.

Nontransient addicts who are well known to the physician sometimes attempt to develop stories similar to those used by the transient, veteran, criminal type of addict. Nontransient addicts, however, are more likely to be sincere than the transient addict. Many such patients truly desire to be cured of their addiction and should be given all possible help. All too frequently, a nontransient addict will be a physician or a nurse. In such cases, the most likely drug of addiction is now meperidine largely because of the widespread belief among the medical profession that this substance is not addicting.

The presenting situation may also be that of an adolescent girl or boy who is brought to the physician by his parents or by other responsible persons. Generally, such adolescents will admit the use of drugs and present no particular problem in diagnosis. In such cases, the physician should exercise a certain degree of care since, because of the widespread publicity concerning addiction in adolescents, many parents may wrongly attribute normal or abnormal adolescent behavior to drug addiction.

When the history leads one to suspect addiction, a complete physical examination is of the utmost importance. A transient addict is frequently surprised when the physician indicates a desire to perform a complete physical examination and may refuse the examination and immediately leave the office. It is important to realize that there are no pathognomonic physical signs of addiction. The opiate drugs do not cause drunkenness as do the barbiturates and alcohol, so mental confusion, emotional instability, nystagmus, and ataxia are not to be expected. Since complete or partial tolerance to many of the effects of morphine develops during the course of addiction, doctors must not expect that addicts presenting themselves in their offices will show the same effects as might be expected in persons not addicted, namely, constriction of the pupils and sedative effects. An addict may or may not show pupillary constriction depending on how recently he has received a dose of morphine. Superficially, tolerant addicts will appear to be physically and mentally normal unless they have been without drugs for some time and signs of abstinence have appeared.

The most important findings are the presence of old and recent needlemarks. These needlemarks should be sought over the veins in the antecubital spaces, the deltoid region, the abdomen, the anterior surface of the thighs, and along the veins of the legs and hands. Multiple abscesses or old abscess scars are also suggestive. Miosis is not a completely reliable sign since partial tolerance to pupillary constriction caused by morphine develops during addiction. Addicts who are using either meperidine or methadone are likely to have induration and inflammation of large areas of the skin, particularly over the deltoid region and the anterior surface of the thighs. Presence of long scars or tattooing over superficial veins is extremely suggestive, particularly if fresh needlemarks are present. One important feature may be that no physical findings are present which satisfactorily explain the serious symptoms detailed by the patient when the history was taken.

Occasionally, persons who are suspected of taking cocaine or marihuana are brought to the physician for an opinion. Neither cocaine nor marihuana produces physical dependence. Since such patients are usually brought to the physician long after the drug effects have worn off, findings are generally scanty. The signs of cocaine intoxication, however, include mydriasis, sweating, tachycardia, increase in blood pressure, increase of deep tendon reflexes, nervousness, tremor, an unblinking stare, and auditory and visual hallucinations. Intoxication with marihuana is characterized by injection of the conjunctivae, a sleepy appearance, excessive giggling, silly behavior, absence of marked ataxia, and a strong odor on the breath resembling that of cubeb cigarettes.

There are no laboratory procedures generally available to the average physician which are helpful in the diagnosis of addiction. Reliable tests for the presence of morphine and cocaine in the urine have been developed, but these methods are quite complex and are not suitable for use in the ordinary laboratory. There are no methods available for the detection of morphine in blood and no laboratory procedures which are sufficiently specific for the detection of synthetic analgesics and marihuana in either blood or urine. Furthermore, if such procedures were available, a positive test of the presence of drugs in the urine would mean only that the person had recently taken or been given a dose of a drug and would not necessarily mean that he was addicted to that drug.

A definitive diagnosis of addiction to morphine or similar drugs depends upon the demonstration of the characteristic signs of abstinence following complete and abrupt withdrawal of drugs. In order to prove the presence of physical dependence, the addict must be isolated in an environment so well controlled that there is no possibility of any narcotic drugs, other than those prescribed, being obtained by the addict. If such an environment is available, isolation of the addict and withholding of all narcotics will prove the presence or absence of dependence on these drugs. The detection of physical dependence requires familiarity with the signs of abstinence from morphine.

If morphine is abruptly withdrawn from a patient who has been receiving as much as 0.26 to 0.39 gm. (4 to 6 grains) daily for a period of 30 days or more, few signs are observed during the first 16 hours of abstinence. The patient is likely to go into a restless, tossing sleep which may last for several hours. About 14 to 18 hours after the last dose of the drug was given, the addict will begin to yawn; rhinorrhea, perspiration, and lacrimation will appear. These mild signs increase in intensity during the first 24 hours of abstinence; thereafter, they become constant. Dilatation of the pupils then appears and, on close observation, recurring waves of gooseflesh will be seen. About 36 hours after the last dose of morphine was given, uncontrollable twitching of the muscles occurs. The patient will become extremely restless, will move from side to side in bed, and tremor of the face and tongue will be evident. The patient will complain of severe cramps in his legs, abdomen, and back; he will be unable to eat or to sleep for any period of time and vomiting and diarrhea frequently occur. Rectal temperature rises about 2 F, respiratory rate is usually elevated to 20 to 30 per minute and is increased in depth. Systolic blood pressure is usually elevated about 15 mm. of mercury, and patients will lose 5 to 15 pounds of weight during the second 24 hours of abstinence. A reduction in eosinophils per cubic millimeter of blood closely parallels the intensity of abstinence symptoms, and, at the peak intensity of the withdrawal illness, the eosinophil count will be nearly zero. This constellation of signs and symptoms constitutes as clear-cut and well delineated a syndrome as is ever seen in clinical medicine. Once it has been observed, it scarcely can be mistaken for any other condition. Acute signs and symptoms reach maximum intensity 48 hours after the last dose of morphine has been given and will remain intense until 72 hours have passed. Thereafter, they gradually subside and, after 5 to 10 days, completely disappear, although the addict may still be weak and sleeping poorly.

It is necessary to remember that the intensity of the abstinence syndrome varies from person to person and is, within limits, dependent on the dose that the addict has been receiving. Not all patients will exhibit all the signs of abstinence listed above. Severe grades of abstinence symptoms are practically always seen in addicts who have been receiving as much as 60 to 90 mg. (1 to 1.5 grains) of morphine four or more times daily. The intensity of abstinence symptoms becomes milder as the average daily dose declines. Since most adolescent addicts actually have been receiving only small amounts of opiates, the effects of abstinence are usually quite mild in juvenile addicts and very close examination may be required to detect the minor signs which are present.

Symptoms of abstinence from other opiates and the synthetic analgesics differ from morphine chiefly in intensity and duration. Effects of abstinence from heroin, dihydromorphinone, and metopon appear very rapidly, reach maximum intensity in 12 hours or less, are somewhat more severe than those from morphine, and subside more rapidly. Abstinence symptoms from codeine appear slowly and are more prolonged than those from morphine. Abstinence symptoms from dihydrocodeinone and eukodal are less intense than those from morphine, but more intense than those from codeine. The symptoms from dromoran® are quite similar in course and intensity to those from morphine.

Effects of abstinence from meperidine appear rapidly and are detectable two to three hours after the last dose of meperidine has been administered. Abstinence from meperidine has an effect somewhat similar to that of abstinence from morphine, but restlessness is even greater, and uncontrollable twitching and jerking of the muscles is extreme. The course of abstinence from meperidine is quite short and symptoms usually disappear two to three days following withdrawal.

Signs of abstinence from methadone come on slowly and are usually not detectable until the third or fourth day after the last dose of the drug has been given. Autonomic signs, such as sweating and mydriasis, are not very prominent. For this reason, the detection of abstinence symptoms is more difficult. The course of abstinence from methadone, however, is quite prolonged. Because of this, withdrawal of methadone is regarded by many addicts as being more uncomfortable than abstinence from morphine.

Frequently, because of the lack of suitable facilities, it may not be possible to isolate the addict and prove the presence of addiction by allowing the signs of abstinence to appear. It is almost useless to attempt to carry out diagnostic withdrawal in a general hospital, or even in mental hospitals, since addicts frequently manage to smuggle drugs into these environments. Diagnostic withdrawal may also be impossible because of the addict's refusal to undergo the procedure and, in certain cases, it may be unwise if the patient has some serious physical disease.

Where adequate isolation for diagnostic withdrawal is not possible, the diagnosis of addiction can be established only tentatively.

A new drug, N-allylnormorphine, which is a very effective antidote for morphine, has recently been shown to precipitate signs of abstinence in addicted persons within 15 minutes following its administration. This agent, therefore, may provide a means of quickly establishing the presence and degree of physical dependence on opiate drugs, but sufficient information on the safety and reliability of the procedure is not available at this time to permit a recommendation for general use of N-allylnormorphine as a diagnostic agent in suspected addiction.

REPORTING OF ADDICTS

The physician is under no legal obligation to report cases of addiction to Federal officials. The Bureau of Narcotics, however, welcomes voluntary reporting of addicts by physicians.

DISPOSITION OF THE ADDICT

Once a tentative diagnosis of addiction has been made, the physician would be well advised to seek consultation for confirmation. The problem then becomes one of advising the addict in accordance with the two cardinal principles of treatment set forth above—institutional treatment is necessary, and drugs must not be given to the addict for self-administration. The addict must be advised to seek admission to an institution for treatment. If he will not accept this advice, the physician may ethically refuse to take any further action. If the patient indicates willingness to undergo institutional treatment, steps should be taken immediately to obtain admission to the nearest and most available institution. Frequently, this can be accomplished immediately by telephoning the institution selected. The physician should refuse to administer any narcotics unless the patient shows the utmost diligence in obtaining entrance into an institution. Such excuses as time for arranging business and personal affairs or preference for one institution over another should not be accepted as reasons for the administration of narcotics; nor should the presence of signs of abstinence be a valid reason for immediate administration of narcotics unless the patient has such serious physical disease that stress of abstinence might prove fatal.

The physician must be prepared to resist the demands of addicts for narcotics and must exercise great care and judgment in determining whether physical disease which requires the immediate administration of opiates is present. If a physician yields to the importunities of an addict and gives him morphine for mild asthma, his waiting room will soon be cluttered with other addicts, all of them complaining that they have asthma or some similar condition. Such a situation can lead only to embarrassment to the physician and, perhaps, to difficulties with the authorities.

When the patient has agreed to go to an institution and has presented satisfactory evidence that he has taken steps to obtain admission (mere statement of the addict is not sufficient evidence of this), the problem is then reduced to the immediate management of the patient. The second principle, drugs should not be given to the addict for self-administration, applies here. It may be possible to place the patient in a general hospital where narcotics can be administered under direct supervision while final arrangements for entrance to the specialized institution are being made. The physician, in any event, should not give the addict a prescription for narcotics but should administer personally such drugs as are appropriate for immediate need only. It may be emphasized that it is always wise to seek consultation with another physician relative to the diagnosis of addiction and/or the presence of serious physical disease. A special record of narcotics administered should be kept, and, as has been previously mentioned, temporary administration of drugs should not be extended beyond the minimum time absolutely necessary for arrangements for admission to an institution to be completed. When the addict leaves his home community, he should be accompanied to the institution, whenever possible, by some responsible person, preferably a physician or a nurse.

No absolute rule can be laid down for the amount of narcotics to be given during the time arrangements for admission to a proper institution are being made. However, no amount of narcotic should be used in excess of that necessary for the immediate need of the patient. Either morphine or methadone may be used since these two drugs will adequately control abstinence from any of the other narcotics. It is advisable to limit the initial dose to 16 mg. (¼ grain) of morphine or 10 mg. (⅙ grain) of methadone. It practically never should be necessary to exceed as a single dose 60 mg. (1 grain) of morphine or 30 mg. (½ grain) of methadone. Even in patients with very severe heart disease, there is little danger of abstinence from morphine causing death if the above dosage schedule is followed. The type of drug given and the dose should be unknown to the addict and all possible precautions should be taken to prevent the addict from obtaining narcotics from other sources.

THE ADOLESCENT ADDICT WITH OR WITHOUT DEMONSTRABLE DEPENDENCE ON NARCOTIC DRUGS

Despite their ages, adolescent addicts must be separated from their usual environments. Institutional treatment for adolescents with demonstrable dependence is just as necessary as for adult addicts and the same procedures should be followed. Adolescents without physical dependence might possibly be sent to a camp, farm, or some other environment where rehabilitative treatment may be attained rather than sent to institutions where contact with older, more hardened addicts is unavoidable.

PATIENTS WITH INCURABLE, FATAL, PAINFUL DISEASES

Persons in this class are usually patients who are dying with advanced carcinoma, tuberculosis, or some other chronic disease. The problem in such instances is completely different from those described above. The physician is properly concerned, primarily, with relieving suffering and, only secondarily, with the addiction. Federal and State narcotic laws were not designed to prevent narcotics from being prescribed in such cases. Proper, ethical medical practice, however, demands that certain principles be followed.

Physicians prescribing narcotics for such patients should personally be attending the patient. A diagnosis of a painful, incurable disease should be confirmed by consultation with another physician. All means of relieving pain other than prescription of narcotics should be exhausted. Such measures include the use of drugs other than narcotics, physical therapy, and surgical procedures designed to relieve pain. When administration of narcotics becomes necessary, the physician should initially use drugs of lesser potency, such as codeine. When use of more potent narcotics is required, they should be given in the smallest possible dose and the interval of administration should be as long as possible. Precautions should be taken to ensure that the amounts of narcotics prescribed are no greater than those actually required for the particular patient so that there will be no surplus for diversion to illicit use. Whenever possible, the drugs should be given orally rather than hypodermically. Drugs should not be given directly to the patient for self-administration. The status of the patient and his disease should be reviewed periodically to make certain that the diagnosis is correct and that definitive, curative therapy is not possible.

COCAINE AND MARIHUANA ADDICTS

Since physical dependence on these drugs does not develop and there is no withdrawal illness, the patient should simply be advised to seek treatment in a properly staffed institution. Hospitalization until admission to an institution can be obtained is not necessary or advisable.

CHOICE OF INSTITUTION

The choice of an institution depends upon the type of case, the financial situation of the patient, and other factors. Many private sanatoriums in the United States make a specialty of the treatment of narcotic drug addiction. Advice concerning these institutions can be obtained from local medical societies, the American Hospital Association, The American Psychiatric Association, or the American Medical Association. Alternatively, the physician may investigate the possibilities of having the patient admitted to a public, local, or state institution. Information concerning such institutions can be obtained by contacting local or state health departments. Lack of suitable local facilities remains one of the difficulties in the treatment of addiction. Physicians should support the establishment of such facilities in states in which no provision for addicts has yet been made. Where local facilities are not available, addicts can be referred to the two federal hospitals maintained by the U. S. Public Health Service at Lexington, Kentucky, and Fort Worth, Texas. Persons addicted to opiates, synthetic analgesics, cocaine, and marihuana are eligible for admission to these institutions. Patients who are addicted to alcohol, barbiturates, or bromides are not eligible for admission to these federal hospitals unless they are also addicted to morphine, synthetic analgesics, marihuana, or cocaine. If the patient is indigent, treatment is available without charge. If the patient has funds, he is required to pay $5.00 daily for his treatment. Addicts entering these institutions are asked to remain at least 135 days before being discharged. Ordinarily, there is no waiting list for male patients and admission can be arranged readily by writing or telephoning the Medical Officer in Charge of either hospital. Only the institution in Lexington has facilities for female patients, consequently, women usually must wait for a short time before they can be admitted.

THE NEED FOR COMPULSION

Unfortunately, many addicts will not go to an institution or remain there until treatment is completed unless compelled to do so by legal means. There is a great need for legislation in most of the states which would make it possible to commit addicts to institutions where they would be forced to remain until maximum benefit of treatment had been obtained. The Federal Bureau of Narcotics has drafted a text of such a proposed law and will distribute copies to interested persons on request. Legislation has also been proposed which would make it possible for the two U. S. Public Health Service Hospitals that treat addicts to accept and hold addicts committed under state laws. Passage of such laws deserves the support of all physicians.

TREATMENT FOLLOWING DISCHARGE FROM INSTITUTION

The follow-up treatment after the patient has been discharged from an institution is usually the weakest link in the overall treatment of addiction, and it is in this particular phase of the problem that the ordinary physician can make the greatest contribution. The physician should do what he can to assist the addict to find a job following discharge from an institution. He can attempt to make arrangements, utilizing such social agencies as are available, to separate the addict from the environment which played a role in engendering the addiction. He should encourage the former addict to participate in the activities of community groups, such as churches and clubs. The physician can advise the relatives of a former addict respecting environmental and familial factors which may be contributing to the patient's difficulties. He can also administer such forms of psychotherapy as he is qualified to carry out. When suitable facilities are available, intensive psychotherapy by a qualified psychiatrist is of great value provided the patient is willing to accept such treatment. The addict should remain under close supervision for at least two years following discharge from an institution. Although the tendency to relapse is very great in addiction, the physician should maintain an optimistic attitude even in the face of repeated recurrence and should continually encourage and support the addict.

MANAGEMENT OF DISEASE IN FORMER ADDICTS

When a person who formerly has been addicted to morphine become afflicted with a disease for which narcotics are usually prescribed (this situation usually develops when a surgical operation becomes necessary), he should be handled just as if he had never been addicted. Since the former addict has been withdrawn from narcotics and has lost his tolerance to them, narcotics should be prescribed in the same doses and at the same intervals as is customary with persons who have never been addicted. Larger doses are not required. Narcotics should never be given to the former addict for self-administration and use of narcotics should be discontinued as soon as possible. The addict should then be supervised closely for a month or so in order to avert relapse to uncontrolled use of drugs.

MANAGEMENT OF ADDICTS WHO HAVE RELAPSED

The management of patients who have relapsed to abusive use of narcotic drugs should follow the same lines as detailed above. The only difference is that the period of supervision following discharge from an institution should be extended.

NEW AND NONOFFICIAL REMEDIES

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application.

R. T. Stormont, M.D., *Secretary.*

Aurothioglucose (See New and Nonofficial Remedies 1952, p. 441).

Schering Corporation, Bloomfield, N. J.

Suspension Solganal in Oil: 1.5 cc. ampuls. A suspension in sesame oil containing 6.7 mg., 16.7 mg., or 33.3 mg. of aurothioglucose in each cubic centimeter with 2% aluminum monostearate. Preserved with 0.1% propylparaben.

10 cc. vials. A suspension in sesame oil containing 10 mg., 50 mg., or 100 mg. of aurothioglucose in each cubic centimeter with 2% aluminum monostearate. Preserved with 0.1% propylparaben. U. S. Trademark 261,372.

Gamma Benzene Hexachloride (See New and Nonofficial Remedies 1952, p. 74).

Commercial Solvents Corporation, New York

Lotion Kwell 1%: 60 cc. and 500 cc. bottles. A lotion containing 10 mg. of gamma benzene hexachloride in each cubic centimeter.

Bismuth Glycolylarsanilate (See New and Nonofficial Remedies 1952, p. 145).

Winthrop-Stearns, Inc., New York

Tablets Milibis: 0.5 gm. U. S. Patent 1,934,017.

Penicillin for Injection for Prolonged Action (See New and Nonofficial Remedies 1952, p. 126).

Merck & Company, Inc., Rahway, N. J.

Procaine Penicillin G for Aqueous Injection: 300,000, 1,500,000, and 3,000,000 unit vials. Buffered with sodium citrate.

Human Pertussis Immune Serum-N.F. (See New and Nonofficial Remedies 1952, p. 380).

Junior League Blood Center of Milwaukee, Inc., Milwaukee

Pertussis Immune Serum (Human): 10 cc. and 20 cc. vials.

CAUTION IN THE CHEMOTHERAPY OF TUBERCULOSIS

Three recently developed antituberculosis drugs, isoniazid (isonicotinic acid hydrazide), iproniazid (1-isonicotinyl-2-isopropyl hydrazine), and pyrazinamide, are now undergoing extensive clinical testing. These drugs have shown definite but limited therapeutic activity against human tuberculosis,[1] but there is much concern among workers in this field that their potential value may rapidly be neutralized if they are used improperly or indiscriminately by those not trained in the treatment of tuberculosis. The recent increase in the availability of isoniazid has brought this problem into acute focus.

One of the major threats to the effective use of the newer forms of tuberculosis chemotherapy lies in the possibility that physicians will attempt to use these drugs as the sole form of therapy. As the American Trudeau Society,[2] the American College of Chest Physicians,[3] and other organizations dealing with tuberculosis have repeatedly emphasized, these compounds are not in themselves cures in spite of the earlier optimistic publicity given to some of them. They, like other forms of chemotherapy, must be used as adjuncts to the time-tested measures of bed rest, collapse therapy, and surgical procedures. Moreover, as adjuncts they have not yet proved clinically superior to, or even so effective as, the combination of streptomycin and *p*-aminosalicylic acid in the treatment of tuberculosis.[2]

Another threat to the continued effectiveness of these drugs arises from the fact, now well established, that the tubercle bacillus is capable of developing resistance to them rapidly both in vitro and in vivo. In the clinic, bacilli resistant to isoniazid, iproniazid [4] and pyrazinamide [1b] have appeared in some cases after only two to four weeks of therapy, although a somewhat longer period is usually required. Such organisms seem to develop especially rapidly in patients with far-advanced cavitary pulmonary tuberculosis, and their appearance is associated with a recurrence of symptoms despite continued treatment. In the laboratory, bacilli with a 5-fold increase in resistance to iproniazid [5] and a 16-fold to 4,000-fold increase in resistance to isoniazid [6] have been obtained by serial passage on media containing these drugs. Resistance to isoniazid, like that to streptomycin, may develop in a single step [7] and may be present in organisms never previously exposed to the drug.[8]

These observations emphasize the need for care in the use of the new drugs. Steenken and co-workers,[9] and Grace and associates (see this issue, page 1241) warn that if these compounds are used alone they may benefit the patient only temporarily and may prejudice his chance of future response to combined drug therapy, surgery, or both. This practice may also result in the widespread appearance of strains of tubercle bacilli resistant to these drugs and in the eventual infection of others with organisms resistant to both streptomycin and isoniazid or one of the other compounds. It is suggested by Grace and associates that these drugs be employed only in multiple combinations with streptomycin and *p*-aminosalicylic acid or other chemotherapeutic agents active against mycobacteria and not related by cross resistance. They base this suggestion on the well-established fact that the production of resistant variants of an organism can be inhibited by simultaneous (but not consecutive) exposure of that organism to at least two drugs with different modes of action. That this general principle applies specifically to isoniazid is suggested by the observation that no tubercle bacilli resistant to either isoniazid or streptomycin have been encountered in cultures exposed simultaneously to therapeutic concentrations of the two drugs,[10] although strains resistant to both have been obtained by successive exposure to these compounds.[7b]

Still another hazard in the use of these drugs is that of inadequate dosage. Since there has not yet been time for adequate long-term evaluation of different dosage schedules for the different forms and stages of tuberculosis, it is obvious that no statement about optimum dosage

or duration of administration can be made. It should be equally obvious that, until such information is available, use of the drugs should be limited to institutions where rigidly controlled observations on different treatment schedules can be made, recorded, and pooled with those of other institutions for final evaluation. Random use of the drugs on an empirical basis can result only in waste, inefficiency, inconclusive results, and harm to some patients.

While there have been few toxic reactions to these drugs to date with the doses used, such reactions must be watched for carefully during and after therapy. According to the Committee on Therapy of the American Trudeau Society, "isolated instances of intractable asthma, persistent hypotension, and increased susceptibility to the effects of other drugs (particularly epinephrine, ephedrine, atropine, and demerol) and even deaths have been reported in patients receiving isoniazid or its isopropyl derivative, but the causal relationship has not been clearly established. Minor untoward effects which have been reported are hyperreflexia, constipation, postural hypotension and dizziness, difficulty in starting micturition, eosinophilia, and the appearance of casts, albumin, and reducing substances in the urine. Routine precautions during treatment should include frequent neurologic examinations, blood counts, urinalyses, and tests for renal and hepatic insufficiency. As both drugs are excreted through the kidneys, impairment of renal function may result in the cumulation of toxic concentrations of the drug in the body. For this reason, the renal function should be measured before treatment and, if it is impaired, the dose should be reduced accordingly." [2]

These facts must be considered carefully by every physician contemplating the use of one of the new drugs in a patient with tuberculosis.

FULL COST TUITION IN MEDICAL SCHOOLS

One of the remedies that has been suggested for the present financial problems that confront the medical schools is that the schools charge their students for the full cost of their education. This suggestion usually is advanced by those not close to medical education, but it has received at least passing attention by a few schools in recent years. Fortunately, the great majority of medical schools have been quick to see the dangers of such a program and have refused to give it serious consideration.

Elsewhere in this issue, page 1243, the Council on Medical Education and Hospitals has an important statement summarizing the many damaging effects that could result from attempts to charge medical students for the full cost of their education. The Council points out that a plan of charging full cost tuition differs only in technical details from the practices of the proprietary medical schools at the beginning of the present century. The Council further gives several reasons why such a program would probably give only temporary relief and in time would actually make the situation of the medical schools worse. It is predicted that such a program would soon discourage support of the medical schools by other sources that have been so carefully cultivated and to whose interest and support much of the present excellence of our medical schools is due.

The school adopting such a program would itself soon suffer greatly. It would be at a serious disadvantage in the competition for able students and would probably find itself largely a school of last choice.

The Council properly fears that the consequences to the ideals and ethics of medical practice that might result from such a plan would be one of its most disastrous features. If medical education is placed on a dollar for dollar basis, the graduate laboring under a large debt could easily be tempted to regard his practice as a business enterprise purchased in the market place to be exploited and commercialized accordingly. Because of these and other inherent and potential dangers, the Council very rightly concludes its statement by condemning plans for charging full cost tuition and by urging the medical schools to continue to cultivate and expand accepted sources of support.

CLOTHING PROTECTION AGAINST RADIATION HAZARDS

In his endless struggle to protect himself against the demands of an exacting environment, man has successfully utilized various types of protective clothing to oppose the destructive action of fire, water, and noxious chemicals. Recently, Holden and Owings [1] called attention to the role of protective clothing in reducing some of the hazards of atomic and radiological warfare. Although clothing does not afford protection against the high neutron and gamma fluxes from an atomic bomb blast, it can protect against alpha, beta, infra-red, and ultraviolet radiations. Following an atomic explosion, an area of variable size is quickly contaminated by radioisotopes emitting alpha, beta, gamma, and x-radiations; in contrast, the hazard found in radiological warfare is due principally to a single type of radiation.

Alpha radiation emanating from an area contaminated by an atomic bomb burst causes damage when it affects the body internally. Effective protection against external contact with alpha radiation is made possible by wearing thin clothing. Ordinarily clothing will reduce a beta-ray flux from combined fission products, but shielding against gamma radiation by means of wearing apparel is impractical today. Since radiation produced by an atomic blast includes beta and gamma rays, this circumstance is analogous to one in which a warrior wearing medieval armor is exposed simultaneously and equally to a combined discharge of arrows and bullets. The armor provides full protection against arrows but incomplete protection against bullets. Similarly, clothing protects adequately against beta rays but inadequately against gamma radiation. All types of radioisotopes are fraught

---

1. Holden, F. R., and Owings, A. F.: Protection Afforded by Clothing Against Radiation Hazards, A. M. A. Arch. Indust. Hyg. 6:67 (July) 1952.

with peril when inhaled or ingested, alpha rays being more damaging locally to internal body structures than beta rays or gamma rays, and beta rays more destructive than gamma rays. Ingestion is due to the transference of radioactive materials from clothing to the mouth via the hands.

While clothing provides limited protection against external radiation, the controlled use of clothing serves not only to lessen body contamination and reduce the dangers of ingestion and inhalation but also to prevent the spread of radiocontaminants. There are numerous instances in which radioactive substances have been transported into previously uncontaminated areas by shoes. The spread of radioisotopes is the atomic age counterpart of Typhoid Mary.

In conclusion, it may be pointed out that the value of protective clothing in atomic and radiological warfare lies in the control of contamination rather than in providing protection against external radiation. The civilian population should be taught to care for itself when trained personnel and decontamination centers are not available. The basic requirements of a decontamination center are laundry facilities, monitoring instruments, and showers that have segregated clean and contaminated areas on either side of them. As for clothing itself, wearing apparel should be light in weight, nonporous, washable or expendable, and should completely cover the body, especially at the wrists, ankles, and the neck. Finally, light-colored clothing reflects infra-red radiation, thereby minimizing burns.

SURVEY OF DISCHARGED MEDICAL PERSONNEL

An increasing number of physicians are being discharged each month from military service after completion of their statutory tour of duty. In some instances dissatisfaction has been expressed with the utilization of medical personnel by the armed forces and the type of duties assigned. In an effort to evaluate the validity of the complaints, the Council on National Emergency Medical Service is contacting all physicians discharged from service since July 1, 1951. The questionnaire being distributed is designed to determine the use made of physicians by the armed services, the amount of time spent on the treatment of other than military personnel, and ways in which the American Medical Association can better serve medical personnel in uniform.

In addition to providing a service to physicians on active duty and those about to enter the armed services, it is hoped that the results of the survey will provide a sound basis for recommendations concerning the "doctor draft law." This law, which was originally enacted on Sept. 9, 1950, with the approval of the American Medical Association, was designed to supply physicians for the armed services. Inasmuch as this act will expire on July 1, 1953, it is necessary to establish a position as to whether legislation of this type should be extended and, if so, the form that it should take.

It is the earnest desire of the American Medical Association to apprize itself of the facts in this regard, to attempt to correct any justifiable source of complaint, and to formulate sound and constructive recommendations with respect to future draft legislation.

SAMPLE OF 1951 PHYSICIANS' INCOMES

On Wednesday of this week the Office of Business Economics of the U. S. Department of Commerce published the results of its interim professional income surveys for physicians, dentists, and lawyers. Unlike the bench mark study of 1949, which involved the analysis of 30,000 replies, the current survey of physicians' incomes is based on less than 1,000 replies from a sample of approximately 5,000 physicians selected by the Bureau of Medical Economic Research of the American Medical Association. The mean net incomes for 1950 and 1951 were $11,538 and $12,518 as compared with $11,058 reported in the big survey of 1949 income.[1]

The key sentence in the report of the 1949 survey published in the Survey of Current Business [2] was: "During the same period [1929-1949], all earners in the general population (wage and salary workers, as well as independent business and professional workers) recorded almost the identical relative increase (109 as compared with 108 percent) as all physicians." The same relationship held in 1950 and 1951 according to the results of this small sample; that is, the average net incomes of physicians are just keeping pace with the rise in the incomes of all earners in the general population. The incomes of the physician and the patient continue to grow apace.

THE NEW KEOGH-REED BILLS

Elsewhere in this issue (page 1244) is an explanation of the new features of the revised Keogh-Reed bills to establish a voluntary pension system. This revised version was introduced in the House of Representatives on June 27, too late to be considered in the closing days of the session. The bills as revised incorporate all the amendments suggested by the American Medical Association. Physicians should acquaint themselves with the provisions of the revised bills so that they can discuss these (identical) bills with other self-employed persons and pensionless employed persons such as lawyers, dentists, farmers, retailers, when they are asked for their opinions. They may also be asked for an opinion by their local candidates for the House and the Senate, as this measure is important to professional men and women.

THE PRESIDENT'S PAGE

A MONTHLY MESSAGE

In going about the country, I have become increasingly convinced that the general public and our own members still need to know more about the American Medical Association and its activities. In certain areas it is regarded by the public as a pressure organization devoted to the interests of management and industry and its own selfish interests. It has the reputation of being undemocratic. Its own members are often too little aware of the vast amount of work done by the Association in education, public health, and in eliminating fraud and charlatanism. The public in many cases believes that the Association limits the number of doctors and is against the socialization of medicine only for pecuniary reasons.

This is a shocking situation, and our public relations must continue to educate both the profession and the public as to the actual facts and must disabuse their minds of all these impressions, none of which are based on fact. In this and succeeding President's pages, I plan to further outline the real status and policies of the Association.

First of all, let us follow an idea that has germinated in the mind of an individual member. This member desires to see the A. M. A. adopt a certain policy that he has outlined in a resolution. There are two courses he can follow. First, he may take the resolution to his county society and introduce it there. He may present his arguments in open meeting, where he can be asked questions. A debate follows. If it is a good idea, his county society may approve the resolution and send it to the state society house of delegates with instructions to the county society delegates to introduce it. It may also circularize other county societies and enlist their support.

This resolution then is introduced into the house of delegates of the state, where it is immediately referred to a reference committee. The proponents of the resolution then appear before the reference committee and argue their case. One does not have to be a member of the house to appear before a reference committee and be heard. The reference committee then accepts, amends, or rejects the resolution and reports to the house. Final action is determined by the house. Again, if it meets with the approval of the majority of the house, it is forwarded to the A. M. A. House of Delegates, where the state's delegates are instructed to introduce it and work for its passage. Again, this may be circulated to other states before the meeting.

In the A. M. A. House of Delegates the same procedure is followed. Again, any member of the A. M. A., whether or not a member of the House, may appear before the Reference Committee and argue on the merits or demerits of the resolution. If the majority of the House concurs, the resolution becomes a part of the policies of the A. M. A. and the Board of Trustees is directed to carry out the policy. A single member, therefore, who holds no office or official position in any body can follow his idea right to the top. What could be more democratic?

Another method that can be followed is for the individual member to ask a member of the House to introduce the resolution direct, where it will follow the usual procedure. I followed this method once, myself. Twenty-three years ago, when I was in the government service, I desired the support of the A. M. A. in a method that was being pursued in the physical selection of airplane pilots. I asked a member of the A. M. A. House to introduce the resolution. I convinced him that approval of it was desirable. He introduced it, and both he and I appeared before the Reference Committee to support it. He was known by the Committee, but I was not, and I did most of the talking and answered most of the questions. I could not have received more courteous attention had I been President of the A. M. A. instead of a completely unknown member. The Reference Committee brought in a favorable report, and the House adopted the Resolution unanimously. Do you know of any other organization in which the individual member has more democratic rights?

Next month I expect to continue this discussion of the A. M. A., its policies, and its relation to the public.

LOUIS H. BAUER, M.D., HEMPSTEAD, N. Y.

ORGANIZATION SECTION

FEDERAL COMMUNICATIONS COMMISSION POSTPONES EFFECTIVE DATE FOR REPLACEMENT OF DIATHERMY EQUIPMENT

The effective date for compliance with the rules of the Federal Communications Commission has been postponed for one year. Physicians or hospitals now using nonconforming short wave diathermy apparatus have until June 30, 1953, to replace the diathermy equipment that does not conform with the rules of the Federal Communications Commission.

The Council on Physical Medicine and Rehabilitation forwarded a petition to the Federal Communications Commission on March 14, 1952, requesting an extension of the final date for one and one-half years. The following reasons were given for an extension. 1. Several thousand physicians and hospitals would be in violation of the rules of the commission or would have to deprive their patients of the therapeutic benefits of diathermy apparatus. 2. The present capacity of the industry to produce ample diathermy appliances was insufficient owing to cut-backs of materials and difficulty in obtaining labor. The Council was supported by several medical and industrial organizations in its request for an extension of time.

In Public Notice 77631, dated June 26, 1952, the Federal Communications Commission announced the extension of the effective date to June 30, 1953. In extending the date the commission pointed out that any further requests for extension of time would be subject to special investigation of individual cases. The commission pointed out the importance of physicians and hospitals equipping themselves with conforming diathermy equipment.

Requests have come to the Council on Physical Medicine and Rehabilitation concerning the possibility of converting short wave diathermy apparatus to conform with the rules of the F. C. C. The Council has been informed by reliable agencies that this is a difficult electrical and mechanical procedure and that the costs involved were as much, if not more, than replacing the equipment with council-accepted and the F. C. C.-approved type of short wave diathermy apparatus. The reconversion of diathermy equipment must be certified by reliable engineers. Surgical diathermy equipment for the generation of electric cutting currents, electric desiccation, and electric coagulation, used only for these medical purposes, are exempt and do not have to be replaced.

HANDBOOK FOR DOCTORS' SECRETARIES

An attractive booklet entitled "Winning Ways with Patients" is the newest A. M. A. public relations aid for physicians. It is a public relations handbook for the physician's secretary, receptionist, or medical assistant, designed to teach medical personnel how to make every patient's contact with the physician or his office staff as pleasant and satisfying as possible.

Because many patients complain "the doctor keeps me waiting too long," one section of the booklet is devoted to techniques for scheduling appointments, fitting patients without appointments and referred patients into the schedule, and keeping patients happy while they are in the waiting room.

Brightly illustrated, "Winning Ways with Patients" discusses telephone techniques, the best methods of billing and collecting medical fees, and other suggestions for improving doctor-patient and secretary-patient relationships. Personality traits, proper office dress, the importance of keeping office confidences, and the various responsibilities of the doctor's assistant are stressed.

This booklet, prepared by the Public Relations Department of the American Medical Association, will be mailed to all physicians in the United States after Aug. 1, and will also be made available to medical societies sponsoring courses for medical secretaries and assistants.

A. M. A. TO SPONSOR PUBLIC RELATIONS INSTITUTE

The American Medical Association's first Public Relations Institute will be held Sept. 4-5 at Chicago's Edgewater Beach Hotel. Featuring clinics covering a variety of practical PR problems, the institute will stress "Putting PR to Work" in local medical society programs. Subjects to be discussed at the two day meeting include increasing member-participation, developing better press-radio-TV relations, working with community groups, strengthening public service activities, carrying on field service activities, editing a society newsletter, utilizing direct mail techniques, and planning radio and TV programs.

Designed primarily for lay public relations personnel of state and county medical societies, the institute will supplement the annual Medical Public Relations Conference to be held Dec. 1, prior to the A. M. A.'s Clinical Session in Denver.

STATE MEDICAL LEGISLATION

Louisiana

Bills Enacted.—H. 219, has become Act No. 202 of the Acts of 1952. It amends and re-enacts the law relating to depositions and discovery by providing, among other things, that in an action in which the mental or physical condition of a party is in controversy, the court in which the act is pending or in which the judgment was originally rendered may order him to submit to a **physical or mental examination by a physician.** The order may be made only on motion for good cause shown and upon notice to the party to be examined and to all other parties and shall specify the time, place, manner, condition, and scope of the examination and the person or persons by whom it is to be made. Reports of such examination shall be delivered to the person examined, or the results of the examination may not be used as evidence at the trial. H. 428 has become Act No. 150 of the Acts of 1952. It provides, among other things, that no body shall be **cremated** except upon the permit or approval of the coroner. H. 429, has become Act No. 151 of the Acts of 1952. It provides, among other things, that by mutual agreement between two-thirds of the coroners of any parish included in any congressional district of the state approved by the police jury of the parish in which such coroner has agreed, there may be established a **forensic laboratory** for the mutual use and benefit of such coroners which shall be at the disposal of the coroners and law enforcement officers of the parish. It also provides that following an autopsy, the coroner may retain any specimens or organs of the deceased which in his discretion are desirable or needful for anatomic, bacteriologic, chemical, or toxicological examination as well as for possible evidence before a grand jury or court. H. 864, has become Act No. 373 of the Acts of 1952. It places all nursing homes under jurisdiction of the state department of health and directs the department of health to provide rules and regulations governing the operation of such homes. It also makes it unlawful for anyone operating a nursing home to administer, **without a doctor's prescription,** any **sleeping potion or medicine or give hypodermic injections** to any inmate of such nursing home. S. 165, has become Act No. 288 of the Acts of 1952. It authorizes charity hospitals of the state to accept as patients persons suffering from **alcoholism.** S. 194, has become Act No. 296 of the Acts of 1952. It puts on a prescription basis the sale and distribution of **barbiturates** and other hypnotic and somnifacient drugs and also **central nervous system stimulants** such as amphetamine and desoxyephedrine. S. 279, has become Act No. 297 of the Acts of 1952. It provides that at least five members of the **state board of health** shall be duly qualified and registered physicians.

Massachusetts

Bills Introduced.—H. 2510, (Appendix E) and H. 2558, propose the creation and **establishment of a state school of medicine** and a state school of dentistry in the City of Boston or vicinity.

Bills Enacted.—H. 2525, Appendix B, has become Resolve No. 84 of the Laws of 1952. It provides for the continuation of a special commission for the purpose of continuing its investigation and study relative to **high blood pressure** and the problem of its control. S. 209, has become Chapter 535 of the Laws of 1952. It authorizes the department of mental health, in connection with the adjudication of restoration of soundness of mind to appoint two physicians certified by the **American Board of Neurology and Psychiatry,** Incorporated, to examine the subject and advise the court of his present mental condition.

Prepared by the Bureau of Legal Medicine and Legislation.

MEDICAL NEWS

CONNECTICUT

Fluoridation of Water Supplies.—The joint conference committee of the Connecticut State Medical Society and the Connecticut State Dental Association has endorsed fluoridation of public water supplies to aid in the control of tooth decay and will recommend to its parent organizations that an educational program be developed to further acquaint the public and community leaders with the benefits of fluoridation. The Connecticut Health League, an organization of 25 state and voluntary health agencies, endorsed water supply fluoridation during its semiannual meeting June 20 at the University of Connecticut, Storrs. Two communities in the state, New Britain and Cromwell, already are fluoridating their water supplies.

Emergency Medical Services.—According to Dr. Edward J. Whalen, Hartford, president of the Connecticut State Medical Society, emergency medical services are now being sponsored by medical associations for more than 1 million Connecticut residents, half the state population. These 24 hour telephone emergency systems are operating in 12 principal communities and are part of a long-range community service program sponsored by the society and its eight component county medical associations. Cities of more than 50,000 population that now have medical association emergency systems in operation include Hartford, New Britain, Waterbury, Bridgeport, and Stamford. Smaller communities where the new systems are operating are Torrington, Danbury, Greenwich, Norwalk, Manchester, Norwich, and Putnam. In addition to the new telephone emergency plan, there are plans mutually arranged between physicians and local hospitals by which patients may obtain emergency medical attention. These plans have proved a valuable service in communities where facilities are inadequate for operation of the emergency telephone systems. The three principal requirements of the new plans are (1) that the system be sponsored and supervised by a medical group or association, (2) that emergency services be available at all times through a central telephone number, and (3) that an organized panel of physicians be available for emergency calls.

ILLINOIS

Dr. Geen Honored.—Dr. James S. Geen of Utica, who has practiced medicine for 50 years and has been a member of the board of the LaSalle County Tuberculosis Sanatorium for 30 years, was honored at a banquet, May 27, in Ottawa. Dr. Geen, who was named to the board of trustees three years after the sanatorium was opened, has served continuously since that time by appointment of the county board of supervisors. He is now president of the board of directors.

State Hospital Needs Help.—The Illinois Department of Public Welfare has issued a call for 153 medical workers to augment the staff of Chicago State Hospital. According to Mr. Fred K. Hoehler, department director, the institution needs 119 attendants, 14 physicians, 3 supervising nurses, 6 psychiatrists, 4 fellows in psychiatry, 1 bacteriologist, 2 dietitians, 1 hydrotherapist, and 3 senior medical students to help in the care and treatment of more than 5,000 patients. The positions are under civil service.

Chicago

Dr. Dragstedt Named Thomas D. Jones Professor.—Dr. Lester R. Dragstedt, chairman of the department of surgery of the University of Chicago Medical Center since 1947, has been named the Thomas D. Jones Distinguished Service Professor of Surgery, to succeed the late Dr. Dallas B. Phemister.

Dr. Dragstedt served as the Nathan Smith Davis professor of physiology and pharmacology and chairman of the department at Northwestern University from 1923 to 1925, when he was appointed to the surgery staff of the University of Chicago. Dr. Dragstedt received the gold medal of the American Medical Association in 1950, the silver medal of the Association in 1947, and the gold medal of the Chicago Medical Society for his work on gastric ulcer.

Cancer Incidence in Chicago Area.—A study of cancer incidence among residents of the Chicago area showed no real change from 1937 to 1947, according to a survey just released by the National Cancer Institute. The study showed a numerical increase, but that was attributed to the aging of the population. The survey results differ from those obtained in five previously published studies, dealing with the metropolitan areas of Atlanta, Denver, New Orleans, Pittsburgh, and San Francisco, where more significant increases in cancer incidence were noted. Dr. John R. Heller, National Cancer Institute director, said, "At present we can only speculate on the meaning of the 'no change' report for the Chicago area. It may, in part, denote geographical differences in cancer incidence. On the other hand, the differences in cancer incidence between Chicago and the other cities may be due in part to improved case-finding and diagnostic techniques. In Chicago there is some indication that diagnostic techniques were already at a fairly high level in 1937."

In the Chicago area, cancer occurs 100 times as often in persons over 65 as in children under 15; however, certain cancers were found to be relatively common in younger persons, notably the leukemias and lymphomas, and soft tissue, bone, and brain tumors. In women, the commonest cancers are those of the breasts, 25%; genital organs, 23%; and digestive system, 27%. In men, 40% of all cancers originate in the digestive system, 13% in the respiratory system, 10% in the genital organs, 8% on the skin, and 8% in the urinary tract. In cancer of the uterus, diagnosed in its early, localized stage, 90% of the patients were found to survive for a year. The survival rate drops to 71% when diagnosis is made after regional involvement, and to 35% when diagnosis follows metastasis. Further, the Chicago data indicate that cancer of the uterus, which is an easily accessible site, is discovered in a localized stage in only 54 of 100 cases. Here, then, is a great need for earlier diagnosis, the report finds. The study also notes that uterine cancer occurs 58% oftener in nonwhite women than in white women. This may be related to the number of pregnancies or the medical care received by mothers during childbirth. The Chicago survey was carried out through the Public Health Service with the cooperation of the Cook County Medical Society, the Chicago Hospital Council, and city and state health departments.

LOUISIANA

Advancement in Rank at Tulane.—Twenty-three advancements in rank among Tulane University's school of medicine faculty have been announced. Faculty members advanced to full professorships include John Adriani (surgery), Paul C. Beaver, Ph.D., (parasitology), Frederick F. Boyce (clinical surgery), Manuel M. Garcia (clinical radiology), Chapman G. Johnson (clinical obstetrics and gynecology), Otto Schales, D.Sc., (biochemistry), Walter S. Wilde, Ph.D., (physiology), and Willard R. Wirth (clinical medicine). New medical associate professorships were granted to Clarence T. Ray (medicine), Isidore L. Robbins (clinical medicine), John R. Snavely (medicine), and Alan G. C. White, Ph.D., (biochemistry). Raised to the rank of assistant professors were Elaine Louise Allen (clinical pediatrics), Jack R. Anderson (clinical otolaryngology), Roger B. Bost (clinical pediatrics), Louis S. Charbonnet (clinical surgery), John K. Hampton Jr., B.S., (physiology), Lee C. Schlesinger (clinical orthopedics), Charles C. Sprague (medicine), Harold G. Tabb (clinical otolaryngology), Walter G. Unglaub (medicine), Richard P. Vieth (clinical pediatrics), and Samuel Zurik (clinical otolaryngology). Dr. Clifford G. Grulee Jr., assistant professor of pediatrics, has been named director of the division of graduate medicine.

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education and public health. Programs should be received at least three weeks before the date of meeting.

MARYLAND

Hospital News.—Dr. Russell A. Nelson has been appointed director of the Johns Hopkins Hospital, Baltimore, to succeed Dr. Edwin L. Crosby, director of the hospital since 1946, who has resigned to become executive head of the Joint Commission for the Accreditation of Hospitals. Dr. Nelson since 1947 has been assistant to Lowell J. Reed, Ph.D., vice-president of the Johns Hopkins University and Hospital.

Narcotic Violation.—Dr. John C. Stewart of Baltimore pleaded not guilty in the state court at Baltimore to a violation of the Uniform Narcotic Drug Act of Maryland and on April 18 was found guilty and sentenced to serve three years. His sentence was suspended, and he was placed on probation, the provisions of which were that he should surrender his narcotic registration. He was also fined $1,000.

MASSACHUSETTS

Society News.—At the annual business meeting of the Massachusetts Heart Association, Dr. Lewis M. Hurxthal of Newton was elected president and Dr. James C. McAdams of Fall River, vice-president. Dr. Benedict F. Massell of Brookline and Mr. Charles E. Cotting of Boston were reelected secretary and treasurer, respectively.

Dr. Hertig Appointed Shattuck Professor.—Dr. Arthur T. Hertig of Boston has been appointed Shattuck Professor of Pathological Anatomy at Harvard Medical School, Boston, to succeed Dr. S. Burt Wolbach, who held that office from 1922 until his retirement in 1947. In 1949 Dr. Hertig and Dr. John Rock, Brookline, won the award of the American Gynecological Society for their study of the development of the early human ovum. Dr. Hertig has been teaching and conducting research in pathology at Harvard Medical School and its associated hospitals since 1932, except for two years (1934-1936) when, as a national research fellow at the Carnegie Institution of Washington, D. C., he was engaged in studying the pathology of embryos. He has been professor of pathology at the Boston Lying-In Hospital and the Free Hospital for Women, Brookline, since 1948 and also has served as consultant to the U. S. Naval Hospital at Chelsea and to the Armed Forces Institute of Pathology.

MISSOURI

Dr. Oscar V. Batson Honored.—The University of Missouri, Columbia, recently conferred the honorary degree of doctor of science on Dr. Oscar V. Batson, professor of anatomy and chairman of the department in the Medico-Chirurgical College, Graduate School of Medicine, University of Pennsylvania, Philadelphia, since 1928, and also assistant professor of otolaryngology at the University of Pennsylvania School of Medicine. Dr. Batson served as instructor in pathology at the University of Missouri School of Medicine, St. Louis, and as instructor in anatomy at the University of Wisconsin, Madison. He later became professor of anatomy at the University of Cincinnati and also at the Ohio College of Dental Surgery before accepting appointment in the Pennsylvania Graduate School of Medicine. He was awarded the Wilhelm Conrad Medal by the American Roentgen Ray Society in 1941 and the bronze medal by the American Medical Association in 1942.

NEW YORK

Society News.—Dr. Carlton E. Wertz, Buffalo, has been appointed chairman of the convention committee for the 1953 annual meeting of the Medical Society of the State of New York to be held next May at Hotel Statler, Buffalo, and Dr. William J. Orr, also of Buffalo, has been designated chairman of the local committee on arrangements.

Gift of Rare Book.—The Lancet Society, an organization of physician-specialists, has presented to the State University of New York College of Medicine at Syracuse a rare book containing the anatomical illustrations of Andreas Vesalius. This volume, given in memory of the late Dr. Henry H. Haft, one of the founders of the society, and clinical professor of medicine at the college of medicine, is one of a number of copies, published jointly by the New York Academy of Medicine and the Library of the University of Munich in Germany, with reproductions from the original wood blocks. These blocks were later destroyed in the bombing of Munich during World War II.

New York City

Hartford Memorial Chapel.—The Pauline A. Hartford Memorial Chapel, a new interdenominational chapel for the use of patients, their relatives, and the hospital staff, was recently dedicated at Columbia-Presbyterian Medical Center. The chapel, a gift of the late John A. Hartford, former board chairman of the Great Atlantic and Pacific Tea Company, is named in honor of his wife, who was a patient at Presbyterian Hospital shortly before her death in 1948.

Alumni Elections.—The Alumni Association of the New York University College of Medicine has elected as president Dr. Anthony S. Bogatko, assistant professor of clinical surgery of the College of Medicine. Dr. Harold Brandaleone, assistant clinical professor of medicine at the college and medical director of the Third Avenue Transit System, was named vice-president.——Dr. James W. Smith, clinical professor of ophthalmology, New York University Post Graduate Medical School, was recently elected vice-president of the Alumni Federation of New York University.

NORTH CAROLINA

Man of the Year.—Dr. Thomas Craven of Huntersville was named "Man of the Year" at a dinner of the Huntersville Lions Club. A scroll was presented by Dr. Edward R. Hipp of Charlotte, president of the Mecklenburg County Medical Society, of which Dr. Craven has been a member for more than 30 years. Dr. Craven has served several terms as mayor of Huntersville and is a member of the Mecklenburg Board of Health, the board of the Mecklenburg Tuberculosis Sanatorium, and the Huntersville School Board.

Postgraduate Program.—The 1952-1953 program of year-round postgraduate medical education at James Walker Memorial Hospital in Wilmington began July 1, with Dr. George T. Harrell, professor of internal medicine and director of the department, Bowman Gray School of Medicine of Wake Forest College, Winston-Salem, as visiting chief. Licensed physicians and medical students are invited to attend the daily conferences held from 5 to 6 p. m., and the clinical pathological conference held each Wednesday at 7:30 p. m. No registration fee is required, but all physicians residing outside New Hanover County are requested to register at the information desk in the lobby of the James Memorial Hospital. During the remainder of 1952, the following visiting chiefs will participate in the program: Aug. 19-22, Dr. Robert L. Sanders, Memphis; Sept. 9-12, Dr. Robert B. Lawson, Winston-Salem; Oct. 7-10, Dr. Richard W. TeLinde, Baltimore; Nov. 4-7, Dr. Charles C. Lund, Boston; Dec. 2-5, Dr. Bradley L. Coley, New York.

OHIO

Doctor's Orchestra.—The Doctor's Orchestra of Akron, under the directorship of Dr. Alexander S. McCormick, in June ended its 26th season with its 159th concert. The next season will open with rehearsals in October.

Centennial of Death of Daniel Drake.—Cincinnati recently observed the centennial of the death of Dr. Daniel Drake, the first physician in Cincinnati to receive a diploma (1805). Dr. Drake founded what is now known as the Cincinnati General Hospital and the University of Cincinnati College of Medicine, serving as its first professor of medicine. He was a pioneer in medical journalism west of the Allegheny mountains, notable among his contributions being the treatise on "The Principal Diseases of the Interior Valleys of North America."

Dr. Marion A. Blankenhorn, professor and chairman, department of internal medicine, University of Cincinnati College of Medicine, was the principal speaker at the Drake tombstone in Spring Grove Cemetery, where a bronze plaque was dedicated, replacing the worn inscription. At a banquet at the Vernon

Manor Hotel, Dr. Frank H. Mayfield, immediate past president, presented to Dr. Cecil Striker, president of the Academy of Medicine, the Daniel Drake gavel, made from the doorsill of Drake's home on Third Street.

A resolution, previously adopted, provides that the new hospital building at the Hamilton County Home is named the Daniel Drake Memorial Hospital. Honorary degrees, conferred by President Raymond Walters of the University of Cincinnati on distinguished guests Dr. Ralph Major of Kansas City, Kan., and Dr. Emmet F. Horine of Brooks, Ky., were previously reported in The Journal. The *Cincinnati Journal of Medicine* entitled its June, 1952, issue the "Daniel Drake Memorial Edition."

PENNSYLVANIA

Physicians Needed.—The Philadelphia Quartermaster Depot, 2800 South 20th Street, Philadelphia, is in need of a full-time (40 hour week) civilian physician. The annual salary is $5,060. For information telephone Mr. Arthur J. Jones, HO 5-2000. A physician is also needed for a summer camp at Pocono Highland, July 27 to Aug. 27. For information telephone Mr. Weinberg, RI 6-0748.

Society News.—The following medical schools of Pennsylvania have made favorable reply to a resolution approved by the House of Delegates of the Medical Society of the State of Pennsylvania recommending the establishment of departments of physical medicine and rehabilitation at the undergraduate and graduate level: the University of Pennsylvania School of Medicine, Temple University School of Medicine, Woman's Medical College of Pennsylvania, Jefferson Medical College, and Hahnemann Medical College, all of Philadelphia, and the University of Pittsburgh School of Medicine.

Philadelphia

Isotope Laboratory.—The Goldman Isotope Laboratory of the Hahnemann Medical College and Hospital of Philadelphia was officially dedicated June 4 at a banquet in honor of Mr. William Goldman, a trustee of the college, who made possible the establishment of the laboratory. Ralph T. Overman, Ph.D., chief of the training section of the Oak Ridge Institute for Nuclear Studies, was the principal speaker.

Pittsburgh

Society Election.—At the meeting of the Pittsburgh Roentgen Society held June 11, the following officers were elected: Dr. William T. Rice, president; Dr. Joseph E. Malia, vice-president; Dr. Donald H. Rice, secretary; Dr. Newton Hornick, treasurer; and Dr. Samuel G. Henderson, counsellor to the American College of Radiology.

SOUTH DAKOTA

Indian Agency Agreement.—The Bureau of Indian Affairs and the South Dakota State Medical Association have entered into an agreement for use of the fee schedule approved by the association, under which medical services of private physicians will be provided. This agreement is for patients referred to private physicians by the superintendent of the reservation involved and for emergency treatment of eligible Indians who may need care away from the reservation. Authorizations issued by the superintendent of the unit involved must accompany each patient referred to private physicians.

WASHINGTON

Haverhill Fever.—Haverhill fever (epidemic arthritic erythema) has been reported in Clark County, Washington. Two cases have been proved by agglutination in high dilution. Discovery of these cases has been credited to Dr. Edward C. Heyde of Vancouver.

Society News.—At the meeting of the Washington State Obstetrical Association, May 3, in Vancouver, B. C., Dr. Clarence W. Knudson of Seattle was elected president; Dr. Kenneth E. Norris of Yakima, vice-president; and Dr. Lincoln B. Donaldson of Seattle, secretary-treasurer.

WEST VIRGINIA

Joint Health and Welfare Meeting.—The West Virginia Welfare Conference, Inc., and the West Virginia Public Health Association will hold a joint meeting at Jackson's Mill, Aug. 22. Dr. Fred J. Holter, Ph.D., graduate advisor in the school of physical education at West Virginia University, will discuss "Community Health Councils." Mr. H. William Millington of Charleston, executive secretary of the Kanawha Welfare Council, will speak on welfare councils; and Mr. Charles Lively, executive secretary, West Virginia State Medical Association, will present a résumé of the association's fifth annual rural health conference held in June. The joint meeting of the 28 member board of the Welfare Conference and the 16 member council of the PHA, the first in the history of the two organizations, has been arranged to correlate the related programs of the two groups.

GENERAL

Society Election.—At the annual meeting of the American Laryngological Association in Toronto, Canada, May 23-24, Dr. Louis H. Clerf, Philadelphia, was elected president; Dr. J. Mackenzie Brown, Los Angeles, first vice-president; Dr. Edwin N. Broyles, Baltimore, second vice-president; Dr. Harry P. Schenck, New York, secretary; and Dr. Gordon F. Harkness, Davenport, Ia., treasurer.

Summer Course in Gerontology.—The New York University summer school at Chautauqua, N. Y., offers a workshop on problems of gerontology and adult education. The course will be given from July 28 to Aug. 8 under the co-direction of Prof. John Carr Duff of the N. Y. U. School of Education and Wilma T. Donahue, Ph.D., director of the division of gerontology at the University of Michigan Human Adjustment Center. Dr. Karl A. Menninger, Topeka, Kan., Harry A. Overstreet, professor emeritus of philosophy, College of the City of New York, and Mrs. Bonaro Overstreet are among the scheduled lecturers.

Outbreaks of Gastroenteritis.—According to the U. S. Public Health Service, an outbreak of food poisoning was reported by the California Department of Public Health. In a fruit pickers' camp about 75 persons became ill after eating sandwiches prepared from ground bologna and boiled eggs. Laboratory examination revealed Staphylococcus albus and alpha hemolytic Streptococcus. The Massachusetts Department of Health reports an outbreak of gastroenteritis in which 84 of 125 persons became ill after a high school banquet. Examination revealed Salmonella typhimurum in nine cases. Another outbreak occurred two weeks later after a banquet served by the same caterer in another high school.

Traffic Accidents in May.—According to the National Safety Council, more Americans were killed by automobiles this May than in any other May on record. The death toll of 3,160 was 12% over May in 1951. The previous high for May was 3,066 deaths in 1937. The May toll boosted the average increase for the first five months of this year to 4% more than for the comparable period last year. Of 42 states reporting for May, 30 had more deaths than in May a year ago, and 12 had fewer.

In contrast with the sharp increase in deaths reported by the states, 441 reporting cities had 5% fewer deaths than in May of last year. Of the 441 cities, 308 reported no traffic deaths in May. The three largest were Providence, R. I. (248,700); Hartford, Conn. (177,400), and New Haven, Conn. (164,400). For five months 156 still had perfect records. The three largest were: Little Rock, Ark. (102,200); Davenport, Ia. (74,500), and Evanston, Ill. (73,600).

Research at Brookhaven National Laboratory.—One hundred and fifty-four visiting scientists and students will participate in the research program at Brookhaven National Laboratory, Upton, L. I., N. Y., this summer, according to Robert A. Patterson, Ph.D., assistant director of the laboratory. This is nearly as many as the total for the 1950 and 1951 summer programs. The summer program will place Brookhaven's special research facilities in the field of atomic energy at the disposal of scientists and students. Of the 1952 group, 63 are scientists who will participate in research projects related to work they conduct at 35 different universities, colleges, or industrial organizations which they represent. Ninety-one are either graduate students or undergraduates from 38 different universities and colleges, who will spend the summer as research assistants in study of atomic energy. Many of the scientists will work in the biology or reactor departments. Brookhaven is the northeastern center for nuclear research and development operated under contract with the AEC by Associated Universities, Inc., a nonprofit educational corporation sponsored by nine leading eastern universities.

Prevalence of Poliomyelitis.—According to the National Office of Vital Statistics, the following number of reported cases of poliomyelitis occurred in the United States, its territories and possessions in the weeks ended as indicated:

Meeting of Persons Subjected to Laryngectomy.—An Institute on Voice Pathology and the first International Meeting of Laryngectomized Persons are announced by the Cleveland Hearing and Speech Center, an affiliate of Western Reserve University. The meeting will be held Aug. 1 and 2 at Harkness Chapel, Bellflower and Ford Drive, on the campus of the university in Cleveland. It is sponsored by the American Cancer Society (Cuyahoga Unit), Cleveland Academy of Medicine, National Cancer Institute of the Institutes of Public Health, Cleveland Otolaryngological Club, the Lost Chord Club of Cleveland, Office of Vocational Rehabilitation of the Federal Security Agency, and the School of Medicine and Speech Department of Western Reserve University.

On Friday, meetings will be held by the sections on laryngeal disease and voice therapy, research on voice, and dysphonias. Saturday morning the sections on surgery in laryngectomy and on rehabilitation of laryngectomized persons will meet. The latter section will present a panel discussion on "Methods of Teaching Esophageal Speech." On Saturday afternoon the first International Meeting of Laryngectomized Persons will be held. Guest speaker at this meeting will be Dr. Charles S. Cameron of New York, president of the American Cancer Society.

The Cleveland Hearing and Speech Center announces that in 1951, 1,992 children and adults received direct therapy and 19,370 persons received indirect service in recreational rehabilitation, public education and training activities. Since 1945, when the center was formed as the result of a merger of the Cleveland Hearing Center and Western Reserve University Speech Clinic, more than 150 laryngectomized persons have been trained in esophageal speech and have participated in the center's Lost Chord Club.

College of Surgeons Meets in New York.—The annual clinical congress of the American College of Surgeons will be held at the Waldorf-Astoria, New York, Sept. 22-26 under the presidency of Dr. Alton Ochsner, New Orleans. On Tuesday a symposium on trauma will be held from 2 to 5 p. m., and at 8:30 p. m. there will be a motion picture symposium on surgery of the heart. On Wednesday a symposium on cancer will be held at 2 p. m. Five panel discussions in gynecology and obstetrics will be held Wednesday, Thursday, and Friday afternoons; problems of neurologic, thoracic, orthopedic, and plastic surgery, and urology will be considered in two panel discussions each on Friday afternoon; and sessions on ophthalmology and otolaryngology will be held Tuesday, Wednesday, and Thursday.

There will be 12 sessions of the forum on fundamental surgical problems, with about 155 papers. Attendance at seven postgraduate courses, to be given from 9 a. m. until noon Tuesday through Friday, is limited to persons registered for them. There will be courses in gynecology and obstetrics, management of fractures, nonmalignant diseases of the gastrointestinal tract, pre and postoperative care of the surgical patient, surgical aspects of pulmonary disease, trauma of the skull and spine, and cardiovascular surgery. The presidential dinner Monday will be followed by an assembly and the presidential meeting. Dr. Donald C. Balfour of Rochester, Minn., will give the 7th Martin Memorial Lecture on "The Evolution of Gastric Surgery." On Wednesday Dr. Sumner L. Koch, Chicago, will give the annual trauma oration and on Friday evening Sir Cecil Wakely of London, England, president of the Royal College of Surgeons, will give the fellowship address at the convocation. A cruise to the Island of Bermuda following the congress has been arranged. Participants will leave New York on Sept. 27 aboard the Queen of Bermuda, returning to New York Oct. 3. Information regarding rates may be obtained from Mr. Leon V. Arnold, 36 Washington Square West, New York 11.

EXAMINATIONS AND LICENSURE

NATIONAL BOARD OF MEDICAL EXAMINERS

NATIONAL BOARD OF MEDICAL EXAMINERS: *Part I*, Sept. 8-10. All centers where there are five or more candidates. Exec. Sec., Dr. John P. Hubbard, 225 S. 15th St., Philadelphia 2.

EXAMINING BOARDS IN SPECIALTIES

AMERICAN BOARD OF ANESTHESIOLOGY: *Oral*. Swampscott, Mass., Sept. 28-Oct. 1. Sec., Dr. C. B. Hickcox, 80 Seymour St., Hartford 15.

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: *Written*. Various Centers, September 1953. Final date for filing applications was May 1. All candidates are now required to take the written examination. *Oral*. Philadelphia, October 1953. Ex. Sec., Miss Janet Newkirk, 66 East 66th St., New York 21.

AMERICAN BOARD OF INTERNAL MEDICINE: *Written*. Various centers and overseas, Oct. 20. Closing date for the acceptance of applications for the written examination was May 1. *Oral*. San Francisco, Sept. 3-6; Philadelphia, Nov. 13-14 and Washington, D. C., Nov. 17-18. Exec. Sec.-Treas., Dr. William A. Werrell, 1 West Main Street, Madison 3.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: *Written*. Various Centers, Feb. 6, 1953. Final date for filing applications is Nov. 1. Sec., Dr. R. L. Faulkner, 2105 Adelbert Road, Cleveland 6.

American Board of Ophthalmology: *Written*. Various Centers, January 1953. Final date for filing applications was July 1. *Practical*. Chicago, Oct. 6-10 and New York City, June 6-10, 1953. Sec., Dr. Edwin B. Dunphy, 56 Ivie Road, Cape Cottage, Maine.

American Board of Orthopaedic Surgery: The deadline for the receipt of applications for the 1953 Part II examinations is Aug. 15. Sec., Dr. Harold A. Sofield, 122 S. Michigan Ave., Chicago.

American Board of Otolaryngology: *Written*. Chicago, Oct. 6-10. *Oral*. Chicago, Oct. 6-10 and April 21-25, 1953. Sec., Dr. Dean M. Lierle, University Hospital, Iowa City.

American Board of Pathology: *Written and Oral*. Pathologic Anatomy and Clinical Pathology examination. Chicago, Oct. 9-11. Sec., Dr. William B. Wartman, 303 E. Chicago Ave., Chicago 11.

American Board of Pediatrics: *Oral*. Chicago, Oct. 24-26; Boston, Dec. 5-7. Exec. Sec., Dr. John McK. Mitchell, 6 Cushman Road, Rosemont, Pa.

American Board of Preventive Medicine and Public Health: Cleveland, Oct. 18-20. Sec., Dr. E. L. Stebbins, 615 N. Wolfe St., Baltimore.

American Board of Proctology: *Oral and Written*. Philadelphia, Sept. 27-28. Sec., Dr. Louis A. Buie, 102-110 Second Ave., S.W., Rochester, Minn.

American Board of Psychiatry and Neurology: New York City, Dec. 15-16. Final date for filing applications is Sept. 15. Sec.-Treas., Dr. David A. Boyd, Jr., 102-110 Second Ave. S.W., Rochester, Minn.

American Board of Radiology: *Oral*. Dec. 1-7. Final date for filing application was June 1. Sec., Dr. B. R. Kirklin, 102-110 Second Ave., S.W., Rochester, Minn.

American Board of Surgery: *Written*. Various Centers. October 1952. Final date for filing application was July 1. *Written*. Various Centers, March 1953. Final date for filing application is Dec. 1. Sec., Dr. J. Stewart Rodman, 225 S. 15th St., Philadelphia.

American Board of Urology: *Written*. Various Centers, December. *Oral*. Chicago, Feb. 7-11. Sec., Dr. Harry Culver, 30 Westwood Road, Minneapolis 16, Minn.

Board of Thoracic Surgery: *Written*. Various Centers, Sept. 5. Sec., Dr. William M. Tuttle, 1151 Taylor Ave , Detroit 2.

MEETINGS

Alaska Territorial Medical Association, Anchorage, Aug. 21-23. Dr. William P. Blanton, P. O. Box 2569, Juneau, Secretary.

American Association of Obstetricians, Gynecologists and Abdominal Surgeons, The Homestead, Hot Springs, Va., Sept. 4-6. Dr. William F. Mengert, 2211 Oak Lawn Ave., Dallas, Texas, Secretary.

American Congress of Physical Medicine, Roosevelt Hotel, New York, Aug. 25-29. Dr. Frances Baker, One Tilton Ave., San Mateo, Calif., Secretary.

American Hospital Association, Philadelphia, Sept. 15-18. Mr. George Bugbee, 18 East Division St., Chicago 10, Executive Director.

American Physiological Socety, New Orleans, Sept. 4-6. Dr. E. F. Adolph, University of Rochester School of Medicine and Dentistry, Rochester, N. Y., Secretary.

American Society of Maxillofacial Surgeons, Hotel del Coronado, San Diego, Calif., Sept. 10-13. Dr. Casper M. Epsteen, 25 East Washington St., Chicago 2, Secretary.

Biological Photographic Association, Hotel New Yorker, New York, Sept. 10-12. Mr. Lloyd E. Varden, Pavelle Color, Inc., 533 W. 57th St., New York 19, Secretary.

Medical Society of Delaware, Rehoboth, Sept. 8-10. Dr. Andrew M. Gehret, 822 North American Bldg., Wilmington, Secretary.

Montana Medical Association, Florence Hotel, Missoula, Sept. 18-21. Mr. L. R. Hegland, 104 North Broadway, Billings, Executive Secretary.

National Medical Association, Chicago, Aug. 11-15. Dr. John T. Givens, 1108 Church St., Norfolk 10, Va., General Secretary.

Neurosurgical Society of America, The Cloister, Sea Island, Ga., Sept. 18-20. Dr. C. D. Hawkes, 22 North Manassas St., Memphis 5, Tenn., Secretary.

Nevada State Medical Association, Reno, Aug. 21-23. Dr. William A. O'Brien III, 505 Chestnut St., Reno, Secretary.

New Hampshire Medical Society, Mt. Washington Hotel, Bretton Woods, Sept. 7-9. Dr. Deering G. Smith, 44 Chester St., Nashua, Secretary.

North Pacific Pediatric Society, Challenger Inn, Sun Valley, Idaho, Sept. 19-20. Dr. S. Gorham Babson, 1107 S.W. 13th Ave., Portland 5, Ore., Secretary.

North Pacific Society of Internal Medicine, Sun Valley, Idaho, Sept. 19-20. Dr. Robert L. King, 1115 Terry Ave., Seattle 1, Wash., Secretary.

North Texas-Southern Oklahoma Fall Clinical Conference, Wichita Falls, Texas, Sept. 17. Dr. E. Aubrey Cox, Hamilton Bldg., Wichita Falls, Texas, Chairman.

Reno Surgical Society Conference, Reno, Nevada, Aug. 21-23. Dr. Olin C. Moulton, 130 N. Virginia St., Reno, Nevada, Chairman.

Rocky Mountain Radiological Society, Denver, Aug. 7-9. Dr. Maurice D. Frazer, 1037 Stuart Bldg., Lincoln, Neb., Secretary.

U. S. Chapter, International College of Surgeons, Conrad Hilton Hotel, Chicago, Sept. 2-5. Dr. Arnold S. Jackson, 1516 Lake Shore Drive, Chicago, Executive Secretary.

Utah State Medical Association, Salt Lake City, Sept. 4-6. Dr. T. C. Weggeland, 42 S. Fifth East St., Salt Lake City, Secretary.

Vermont State Medical Society, Mt. Washington Hotel, Bretton Woods, N. H., Sept. 7-9. Dr. James P. Hammond, 128 Merchants Row, Rutland, Secretary.

Washington State Medical Association, Olympic Hotel, Seattle, Sept. 13-17. Dr. Bruce Zimmerman, 338 White-Henry-Stuart Bldg., Seattle, Secretary.

INTERNATIONAL

American Congress of Industrial Medicine, Rio de Janeiro, Brazil, Sept. 20-28. General Secretarial Office: Calle Arenales No. 981 Buenos Aires, Argentina.

Australasian Medical Congress, Melbourne Victoria, Australia, Aug. 22-30. Dr. C. H. Dickson, Medical Society Hall, 426 Albert St., East Melbourne, Victoria, Australia, General Secretary.

European Congress of Cardiology. University of London, Bloomsbury, W.C.1, England, Sept. 10-12. Dr. K. Shirley Smith, 35 Wimpole St., London, W.1, England, Secretary.

European Society of Cardiovascular Surgery, Strasbourg, France, Oct. 3-4. Sir James Learmonth, Department of Surgery, University New Buildings, Edinburgh 8, Scotland.

Interamerican Cardiological Congress, Buenos Aires, Argentina, Aug. 31-Sept. 7. Dr. Blas Moia, Larrea 1132, Buenos Aires, Argentina, Secretary-General.

Inter-American Congress of Public Health, Havana, Cuba. Sept. 26-Oct. 1. Pan-American Sanitary Bureau, 2001 Connecticut Ave., Washington, D. C.

Inter-American Congress of Radiology, Mexico City, Mexico, Nov. 2-8. Dr. Guido Torres Martinez, Marsella No. 11, Mexico, D.F., Secretary-General.

International Congress of Anthropology and Ethnology, Vienna, Austria, Sept. 1-8. For information write: Secretaries, Royal Anthropological Institute, 52 Upper Bedford Place, London, W.C.1, England.

International Congress on Diseases of the Chest, Rio de Janeiro, Brazil, Aug. 24-30. Mr. Murray Kornfeld, 112 East Chestnut St., Chicago 11, Illinois, Executive Secretary.

International Congress of Haematology, Mar del Plata, Argentina, Sept. 21-26. Dr. Carlos Reussi, Anchorena 1710, Buenos Aires, Argentina, Secretary.

International Congress of the History of Medicine, Nice-Cannes, France, and Monaco, Sept. 8-14. Dr. F. A. Sondervorst, 124 Avenue des Allies, Louvain, Belgium, Secretary-General.

International Congress on Hydatid Disease, Santiago, Chile, Nov. 21-24. Organizing Committee, P. O. Box 9183, Santiago, Chile.

International Congress of Internal Medicine, Friends House, London, N.W.1, Eng. Sept. 15-18. Sir Harold Boldero, 12 Pall Mall East, London, S.W.1, England, Secretary.

International Congress of Medical Press, Venice, Italy, Oct. 4-5. Dr. Bruno de Biasio, S. Marco 4646, Venice, Italy, Secretary.

International Congress on Medical Records, London, England, Sept. 7-12. Miss Gwen Perkins, 120 C Street S.E., Washington, D. C., Chairman.

International Congress of Military Medicine and Pharmacy, Montevideo, Uruguay, March 1-7, 1953. Dirreccion General del Servico de Sanitad Militar, 8 de Octubre y Mariano Moreno, Montevideo, Uruguay, Secretariat of the Congress.

International Congress on Neuropathology, Rome, Italy, Sept. 8-13. Dr. Armando Ferraro, 722 W. 168th St., New York, N. Y., U. S. A., Secretary General.

International Congress of Otorhinolaryngology, Amsterdam, Netherlands, June 8-15, 1953. Dr. W. H. Struben, J. J. Viottastraat 1, Amsterdam, Netherlands, Secretary.

International Congress of Urology, The Waldorf-Astoria, New York, N. Y., U. S. A., Sept. 15-18. Dr. John A. Taylor, 2 East 54th St., New York, N. Y., U. S. A., Secretary-General.

International Hospital Congress, London, England, May 25-30, 1953. Capt. J. E. Stone, 10 Old Jewry, London, EC2, England, Hon. Secretary.

International Study Conference on Child Welfare, Bombay, India, Dec. 5-12. For information write: All India Save the Children Committee, 5 Carmichael Road, Bombay, India.

International Union Against Tuberculosis, Rio de Janeiro, Brazil, Aug. 24-27. Prof. Etienne Bernard, 66 Blvd. St. Michel, Paris 6e, France, Secretary-General.

Medical Women's International Association, Vichy, France, Sept. 12-16. Dr. Margaret M. Wurts, 27 East Wellesley Road, Montclair, N. J., U. S. A., National Secretary.

Neuroradiologic Symposium, Stockholm, Sweden, Sept. 17-20. Docent Ake Lindbom, Symposium Neuroradiologicum, Serafimerlasarettet, Stockholm K., Sweden, Secretary.

World Congress of Jewish Physicians, Jerusalem, Israel, Aug. 10-14. Secretariat: ℅ Israel Medical Association, Rehov Mesilat Yesharim, Beth Kovatz, Jerusalem, Israel.

World Congress of Medicine, Montecatini, Italy, Oct. 16-18. Secretariat: Corso Trieste, 65, Rome, Italy.

World Federation of Mental Health, Brussels, Belgium, Aug. 25-Sept. 1. Dr. J. R. Rees, 19 Manchester St., London, W.1, England, Secretary.

World Medical Association, Athens, Greece, Oct. 12-16. Dr. Louis H. Bauer, 2 East 103d St., New York 29, N. Y., Secretary General

DEATHS

Ireland, Merritte Weber ⊕ major general, U. S. Army, retired, Washington, D. C., formerly, for more than 12 years, Surgeon General of the Army, died in Walter Reed Hospital July 5, aged 85. Born in Columbia City, Ind., the son of a physician, General Ireland received his first degree in medicine from the Detroit College of Medicine in 1890. He received a second degree from Jefferson Medical College in Philadelphia the following year and then was commissioned an assistant surgeon in the Army. He served in Cuba during the Spanish-American War. During the Mexican expedition led by Gen. John J. Pershing he was post surgeon at Fort Sam Houston, Texas and later went to France with General Pershing, where he headed the medical service of the American Expeditionary Force. General Ireland was largely responsible for the development of modern concepts of field medicine during World War I. He served as Surgeon General from Oct. 4, 1918, until his retirement from the Army on May 31, 1931. His term of office saw the creation of the Army Medical Center on the grounds of Walter Reed Army Hospital. Among General Ireland's awards were the Distinguished Service Medal, Commander of the Legion of Honor of France, Companion of the Order of the Bath of Great Britain, and Grand Officer of the Order of Polonia Restituta. In 1945 he was awarded the William Freeman Snow Medal for distinguished service to humanity from the American Social Hygiene Association, and in April, 1945, received a citation for distinguished service to humanity from the Medical Society of the District of Columbia. General Ireland served as a delegate from the U. S. Army to the American Medical Association in 1908, 1909, and 1910, and later was a member of its Council on Medical Education and Hospitals. He was past president of the National Board of Medical Examiners, Association of the Military Surgeons of the United States, and the American College of Surgeons. He was formerly secretary of the Gorgas Memorial Institute of Tropical and Preventive Medicine, a fellow and ex-governor of the American College of Physicians, a fellow of the Royal College of Surgeons of Edinburgh, and a member of the American Psychiatric Association. He had been a director of the Columbia Hospital for Women and Lying-In Asylum, Garfield Memorial Hospital, and the United States Soldiers Home Hospital. He delivered the William Potter Memorial Lecture at Jefferson Medical College in 1939. In 1947 he resigned as president of the Army Mutual Aid Association after 18 years of service and as a director of that organization for 32 years. General Ireland received LL.D. degrees from Jefferson in 1919, Gettysburg (Pa.) College in 1922, and Syracuse (N. Y.) University in 1935 and an A.M degree from the University of Michigan in Ann Arbor in 1920.

LeBel, Louis Jean Baptiste ⊕ Nutley, N. J.; born in Nutley, N. J., Jan. 26, 1895; University of Virginia Department of Medicine, Charlottesville, 1921; specialist certified by the American Board of Dermatology and Syphilology; founder and a past president of the Northern New Jersey Dermatological Society; member of the American Academy of Dermatology and Syphilology; member of the professional staff, Council on Medical Education and Hospitals, American Medical Association in Chicago; at one time taught at Columbia University College of Physicians and Surgeons in New York; for many years affiliated with St. Mary's Hospital in Passaic, where he was president of the medical staff from 1939 to 1941 and where he died May 20, aged 57, of subacute bacterial endocarditis.

Curtis, Elmer Eaton ⊕ medical director, captain, U. S. Navy (retired), Vallejo, Calif.; born in Hiawatha, Kan., Aug. 7, 1877; St. Louis University School of Medicine, 1905; commissioned a lieutenant (jg) in the Medical Corps of the U. S. Navy on July 12, 1907; attained the rank of captain on July 1, 1929, and on Sept. 1, 1941, was placed on the retired list; during World War I served aboard the transports USS Powhatan and USS Mount Vernon, engaged in ferrying troops across the Atlantic; after attending the Naval War College, Newport, R. I., in 1933 was assigned to the staff of the commander, Battle Force, U. S. Fleet, as force medical officer; recalled to active duty at the outbreak of World War II, and assigned as medical officer in command of the Naval Dispensary, Treasure Island, Calif.; in 1942, assumed command of the Naval Hospital, Treasure Island, San Francisco; was released from active duty in 1945 and returned to the retired list; died in the Naval Hospital, Mare Island, May 5, aged 74, of lymphosarcoma of small intestine, peritonitis and bronchopneumonia.

Levy, Joseph ⊕ New Rochelle, N. Y.; born in New York April 10, 1901; Johns Hopkins University School of Medicine, Baltimore, 1927; specialist certified by the American Board of Internal Medicine; fellow of the American College of Physicians; member of the Latin American Congress of Physical Medicine, Aero Medical Association, International Society of Internal Medicine, American Academy of Sciences, American Geriatrics Society, Israel Medical Association, Westchester Heart Association, and New Rochelle Hospital Association; member of the Phi Delta Epsilon Fraternity and a founder of Tau Alpha Omega, a fraternity at City College; during World War II a flight surgeon with the rank of major in the Army Medical Corps, serving in Africa and the Philippines; adjunct physician, Montefiore Hospital for Chronic Diseases in New York; attending physician, New Rochelle Hospital; died in San José, Costa Rica, recently, aged 50, of coronary occlusion, after delivering a paper at the fourth annual convention of the Latin American Congress of Physical Medicine.

Jostes, Frederick Augustus ⊕ St. Louis; born in St. Louis Aug. 14, 1895; Washington University School of Medicine, St. Louis, 1920; specialist certified by the American Board of Orthopaedic Surgery; member of the American Orthopaedic Association, Clinical Orthopaedic Society, and the American Academy of Orthopaedic Surgeons; fellow of the American College of Surgeons; president of the Missouri Society for Crippled Children and Adults and first vice-president of the Mississippi Valley Medical Society; served during World War II; assistant professor of clinical orthopedic surgery at his alma mater; affiliated with St. Louis County Hospital in Clayton, Bernard Free Skin and Cancer Hospital, Evangelical Deaconess, St. Louis Children's, and Jewish hospitals, and the Barnes Hospital, where he died May 19, aged 56, of lymphosarcoma.

White, Vivian Parley ⊕ Salt Lake City; born in Salt Lake City, Sept. 12, 1896; Harvard Medical School, Boston, 1923; specialist certified by the American Board of Otolaryngology; member of the American Academy of Ophthalmology and Otolaryngology and the Pacific Coast Oto-Ophthalmological Society, of which he had been vice-president; immediate past president of Utah State Medical Association; past president of the Utah State Ophthalmological Society; clinical lecturer in surgery (otolaryngology) at the University of Utah College of Medicine, where he had been instructor in anatomy of the head and neck from 1925 to 1927; affiliated with Salt Lake County General Hospital and Dr. W. H. Groves Latter-Day Saints Hospital, where he died May 13, aged 55, of carcinoma of the intestine.

Albanese, Nicholas Anthony ⊕ Columbus, Ohio; Starling-Ohio Medical College, Columbus, 1914; served during World Wars I and II; affiliated with St. Ann's Maternity Hospital; died April 26, aged 59, of myocardial infarction.

Bartholomew, Alfred Castle ⊕ Fort Wayne, Ind.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1901; served during World War I; died in Methodist Hospital April 27, aged 73, of myocardial infarction.

Bennett, Charles Lenzo ⊕ Kalamazoo, Mich.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1904; past president of the Kalamazoo Academy of Medicine; formerly practiced in Gobleville, where he had been on the village council and school board; formerly vice-president and

---

⊕ Indicates Member of the American Medical Association.

director of the State Bank in Gobles; affiliated with Bronson Hospital and Borgess Hospital, where he died April 22, aged 76, of pneumonia and arteriosclerotic heart disease.

Denison, Edward Lyman, Jensen Beach, Fla.; Northwestern Medical College, St. Joseph, Mo., 1892; Illinois Medical College, Chicago, 1895; formerly practiced in Chicago, where he was affiliated with St. Luke's Hospital; died April 27, aged 82, of coronary occlusion.

Elias, Francis Leander ⊕ Wymore, Neb.; University of Kansas School of Medicine, Kansas City, 1910; past president of Gage County Medical Society; affiliated with Lutheran Hospital in Beatrice, where he died March 3, aged 68, of coronary thrombosis.

Flowers, Earl Newton ⊕ Clarksburg, W. Va.; Johns Hopkins University School of Medicine, Baltimore, 1919; served as city health officer; veteran of World War I; died April 12, aged 57.

Gaskill, Henry Kennedy ⊕ Hendersonville, N. C.; Jefferson Medical College of Philadelphia, 1906; member of the Medical Society of the State of Pennsylvania; formerly practiced in Philadelphia, where he was professor of dermatology at the Woman's Medical College of Pennsylvania; served during World War I; died April 11, aged 79 .

Gulbrandsen, Lyder Oliver ⊕ Viroqua, Wis.; Marquette University School of Medicine, Milwaukee, 1927; served during World Wars I and II; died in La Crosse, recently, aged 51, of coronary occlusion.

Hamer, Clemen ⊕ Glendale, Calif.; College of Medical Evangelists, Loma Linda and Los Angeles, 1924; affiliated with Behrens Memorial Hospital, Physicians and Surgeons Hospital, and Glendale Sanitarium and Hospital, where he was a member of the board of directors and where he died April 1, aged 68, of pneumonia.

Hemstead, Werner ⊕ Minneapolis; Omaha Medical College, 1882; died in Rochester, Minn., March 11, aged 91, of bronchopneumonia and cerebral infarcts.

Henriksen, Henry George, Northfield, Minn.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1897; also a graduate in pharmacy; died March 30, aged 82, of carcinoma of the lungs.

Herzog, Charles E. ⊕ Stormville, N. Y.; Long Island College Hospital, Brooklyn, 1922; connected with the Department of Correction; killed April 23, aged 53, when his automobile collided with a truck.

Hirst, Jesse Watson, St. Petersburg, Fla.; Jefferson Medical College of Philadelphia, 1893; for many years a Presbyterian medical missionary in Korea, and at one time court physician to the emperor; died in St. Anthony's Hospital April 28, aged 88, of cerebral vascular accident.

Hively, Howard Dayton ⊕ Parkersburg, W. Va.; University of Louisville (Ky.) Medical Department, 1912; formerly medical director of the West Virginia Coal and Coke Corporation in Omar; at one time practiced in Charleston, where he was affiliated with Charleston General Hospital; died April 7, aged 66, of coronary thrombosis and arteriosclerosis.

Hodgson, Thomas Cady ⊕ Berlin, Conn.; University of Toronto Faculty of Medicine, Toronto, Canada, 1894; served as health officer and medical examiner; died in Hartford April 21, aged 82, of internal carotid thrombosis.

Hofmann, Erich Manfred ⊕ Wooster, Ohio; Thüringische Landesuniversität Medizinische Fakultät, Jena, Thuringia, Germany, 1919; died March 4, aged 63.

Hopper, Henry Paine, Saucier, Miss.; Kentucky School of Medicine, Louisville, 1904; for many years county physician; died in the Veterans Administration Hospital, Biloxi, April 3, aged 78, of pulmonary edema and arteriosclerotic heart disease.

Hutchings, Charles Wyatt ⊕ Syracuse, N. Y.; Syracuse University College of Medicine, 1926; member of the American Psychiatric Association; served during World War II; assistant director of the Syracuse State School of the New York State Department of Mental Hygiene, Fairmount; formerly on the staff of the Marcy (N. Y.) State Hospital and assistant director of the Manhattan State Hospital, Wards Island, New York City; died in Syracuse Memorial Hospital April 15, aged 52, following a gastrectomy.

Imbrie, Clarence Elwood ⊕ Butler, Pa.; Baltimore Medical College, 1904; affiliated with Butler County Memorial Hospital; died April 13, aged 77, of coronary occlusion.

MacDonald, Aeneas E. ⊕ Minneapolis; Queen's University Faculty of Medicine, Kingston, Canada, 1901; affiliated with St. Mary's and Asbury hospitals; died April 11, aged 76, of cerebral hemorrhage and arteriosclerosis.

McGarvah, Joseph Andrew ⊕ Detroit; Detroit College of Medicine, 1905; affiliated with Woman's Hospital; died March 20, aged 69, of carcinoma of the bile ducts.

Madison, William Davis ⊕ Peoria, Ill.; Drake University College of Medicine, Des Moines, 1912; affiliated with Florence Crittenton Home and Methodist Hospital, where he died April 28, aged 69, of coronary thrombosis.

Marcussen, Robert Monroe ⊕ Menlo Park, Calif.; Cornell University Medical College, New York, 1943; city councilman; served during World War II; Commonwealth Fund Fellow in Medicine at his alma mater, 1947-1948; in 1949-1950 Fellow in Neuropsychiatry at Stanford University School of Medicine in San Francisco, where he had been clinical instructor in medicine; died April 13, aged 33.

Martin, Solomon Claiborne Jr., West Palm Peach, Fla.; Barnes Medical College, St. Louis, 1893; died recently, aged 81, of myocardial disease and congestive heart failure.

Massoud, Mittry Abi ⊕ Pineora, Ga.; Maryland Medical College, Baltimore, 1904; died April 30, aged 76, of coronary heart disease.

Maxson, John Child, Campbell, Calif.; University Medical College of Kansas City, Mo., 1893; served during World War I; died in San Jose March 29, aged 85, of mesenteric thrombosis.

Merrill, Adelbert Samuel ⊕ Manchester, N. H.; Tufts College Medical School, Boston, 1908; specialist certified by the American Board of Radiology; member of the American Roentgen Ray Society, New England Roentgen Ray Society and the American College of Radiology; affiliated with Elliott Hospital; died in Concord April 7, aged 76.

Mitchell, Robert Lee ⊕ Vinita, Okla.; University of Arkansas School of Medicine, Little Rock, 1904; served overseas during World War I; affiliated with Eastern State Hospital; at one time on the staff of Veterans Administration Hospital in Houston, Texas; for many years affiliated with Veterans Administration Hospital in Muskogee, where he died May 15, aged 76, of coronary thrombosis.

Moncure, Turner Ashby, Baltimore; Medical College of Virginia, Richmond, 1912; clinic chief of the Presbyterian Eye, Ear and Throat Charity Hospital; died in the Lutheran Hospital April 23, aged 65, of arteriosclerotic cardiovascular disease.

Simmons, James Franklin, Greenville, Miss.; Mississippi Medical College, Meridian, 1907; on the staff of the Kings Daughters Hospital; died March 27, aged 68, of cerebral hemorrhage.

Smith, John McNeill ⊕ Rowland, N. C.; Jefferson Medical College of Philadelphia, 1908; died recently, aged 67, of cerebral hemorrhage and arteriosclerosis.

Townsend, Mary Ella, Atlantic City, N. J.; Woman's Medical College of Pennsylvania, Philadelphia, 1895; died in Camden March 11, aged 83, following an operation for cancer.

White, Thomas Francis ⊕ Baltimore; University of Maryland School of Medicine, and College of Physicians and Surgeons, Baltimore, 1920; served as health officer-at-large for Baltimore City; died March 6, aged 61, of coronary thrombosis.

Willson, Pleas, Newborn, Ga.; Atlanta College of Physicians and Surgeons, 1901; died March 14, aged 71, of cerebral hemorrhage and hypertension.

Young, Louise Sanford, El Paso, Texas; Illinois Medical College, Chicago, 1905; University of Louisville (Ky.) Medical Department, 1905; died April 20, aged 83, of arteriosclerosis.

GOVERNMENT SERVICES

NAVY

Construction Projects to Provide 2,300 Hospital Beds.—Plans to build a new permanent hospital at Norfolk, Va., and major permanent additions to existing hospitals at Great Lakes, Ill., and San Diego, Calif., have been announced by the Navy. The construction, which will begin next year, will provide a total of 2,300 additional beds. The largest of the projects will be a 1,000 bed addition to the naval hospital at San Diego. The addition will be a multistory structure and will include operating rooms, x-ray facilities, and messing areas.

The new hospital to augment medical facilities in the Norfolk area will contain 800 beds initially, with provision for expansion to 1,500 beds. The 500-bed addition to the naval hospital at the Great Lakes Naval Training Center will be a multistory permanent structure. The original hospital was built in 1911.

Study of Protein Metabolism.—Henry Borsook, professor of biochemistry at the California Institute of Technology, addressed the Naval School of Aviation Medicine at Pensacola on July 7 on "Newer Aspects of Protein Metabolism." Dr. Borsook was on his way to Paris, where he will lecture on that subject. While in Pensacola he completed initial planning with Captain Ashton Graybiel (MC), Director of Research, and Capt. James L. Rolland (MC), Commanding Officer, preparatory to setting up a cooperative study on protein metabolism sponsored by the California Institute of Technology and the U. S. Naval School of Aviation Medicine.

Personal.—Capt. C. W. Shilling (MC) director, research division, Bureau of Medicine and Surgery, was guest speaker at the annual open house of the Worcester Foundation for Experimental Biology June 14. Captain Shilling spoke on "The Usefulness of Useless Research." Captain Shilling also attended the dedication of the Aviation Medical Acceleration Laboratory at Johnsville, Pa., June 17.

AIR FORCE

Study of Human Adaptation to High Altitudes.—Brig. Gen. Otis O. Benson Jr., commandant of the Air Force School of Aviation Medicine, and a party of military and civilian scientists, have flown to a remote laboratory in Peru, where human adaptation to high altitudes is being investigated. The Institute of Andean Biology, an outpost of the University of San Marcos in Lima, is perched on the upper slopes of the Andes at the mining town of Morococha, one of the loftiest inhabited spots on earth. The town is 90 miles from Peru's sea-coast capital on a plateau 14,900 feet up.

Dr. Alberto Hurtado, the Peruvian physician who runs the Institute, is a Harvard graduate and former research worker at the Mayo Foundation. He has chosen the Indian descendants of the Incas who live on the towering heights of his native land for his special field of study.

The Indians at Morococha toil in the mines at altitudes up to 18,000 ft., where an Air Force flyer is required to wear an oxygen mask, and for relaxation play football in the hard-driving English style. The changes in their physiological processes after centuries of existence on those dizzy heights are of vital interest to the Air Force.

Dr. Hurtado holds a contract with the Air Force to learn what these changes are, and to search for possible ways in which they might be speeded up. It is to settle the final terms of this contract that General Benson's group is flying to Peru. The School of Aviation Medicine is the Air Force research organization which administers the high-altitude project. With the General are other specialists, among them Col. Paul A. Campbell, director of research at the aeromedical school. From the University of California at Berkeley, Dr. John H. Lawrence, director of the Donner Laboratory of Medical Physics, and William Siri, a research physicist, flew to Randolph Field to join the party. Also in the group is Dr. Peter Hoessly, assistant professor of medicine at the University of Utah.

VETERANS ADMINISTRATION

Increased Pay for Disabled Veterans.—Almost 120,000 blind, crippled and tuberculous veterans of all wars and peacetime service will receive increased payments in their compensation checks due Sept. 1, 1952, under Public Law 427 signed by the President June 30. Veterans who are not on the compensation rolls and are covered by the new law should apply at their nearest VA Regional Office.

Veterans who will receive the increased checks are those who have been awarded statutory allowances for the loss, or loss of use, of either or both hands or feet, for blindness, and for total deafness (in combination with total blindness). Veterans who are receiving a minimum monthly rate of compensation for arrested tuberculosis will also receive increased checks. Statutory allowances are paid in addition to the basic compensation rates, which are based on the degree of disability and range from $15.75 to $172.50.

The new law authorizes for the first time for World War II veterans and veterans with service since the beginning of the Korean conflict a minimum monthly rate for arrested tuberculosis and a statutory allowance for the loss, or loss of use, of a creative organ. Up to now these benefits have been available under existing law to certain World War I veterans only. Following are the increases for veterans disabled in wartime or since the Korean conflict started:

1. Monthly statutory allowance for the anatomical loss, or loss of use, of one hand or one foot, or blindness of one eye (having only light perception) increased from $42 to $47. This is payable in addition to monthly rate of compensation.

2. Monthly rate of compensation for the anatomical loss, or loss of use, of both hands, both feet, blindness, total deafness (in combination with total blindness), and various combinations of such disabilities increased from a range of $240 to $360, to a range of $266 to $400. Additional amounts are payable for a wife, children, or dependent parents in these cases and in all other service-connected cases in which the veteran's disability is rated 50% or more. The monthly rates of such additional compensation in totally disabled cases range from $21 to $91, depending on the number and type of dependents. The new law does not increase these additional amounts.

3. The minimum monthly rate of compensation for service-incurred tuberculosis that has been arrested is increased from $60 to $67 and extended to cover World War II veterans and veterans with service since the start of the Korean conflict.

4. Monthly statutory allowance for loss, or loss of use, of creative organ is increased from $30 to $47 and extended to cover World War II veterans and veterans with service since the start of the Korean conflict.

5. Certain seriously disabled World War I veterans, with service-connected disabilities, will receive increased monthly payments—from $198 to $220 for totally blind veterans; from $258 to $286 for totally blind veterans who have lost one or more limbs; and from $60 to $67 for veterans who need the regular aid and attendance of another person.

These new wartime rates also are payable for peacetime service if the specific disabilities were incurred in line of duty as the direct result of armed conflict or while engaged in extra hazardous service, including service under conditions simulating war. Rates of compensation for disabilities incurred during other peacetime service are 80% of wartime rates.

FOREIGN LETTERS

BRAZIL

International Congress of Surgery.—The International Congress of Surgery was held at Madrid, from May 19 to 25, and was attended by more than 2,000 surgeons of many different specialties, coming from 37 countries. Some 500 papers were presented, and films were shown to demonstrate various surgical techniques. For the first time in Europe, with the cooperation of Remington Rand Inc., color television was produced by the "vericolor" process, and these operations were transmitted on television from the "Cidade Universitaria" (University Town). At the closing ceremony, paying special homage to the memory of the great Spanish scientist Ramon y Cajal, the following speakers were heard: the minister of education, the dean of the university, Prof. Gregorio Marañon, and the secretary of the International Congress, Prof. Alfonso de la Fuente. During this ceremony the head of the Brazilian delegation, Prof. Rodolfo de Freitas, acknowledged the privilege of São Paulo being the place chosen for the 9th International Congress of Surgery and invited surgeons from all over the world to visit Brazil in 1954. At the meeting of the house of delegates it was decided that a building be constructed in São Paulo as a center for meetings of the members of the "Capítulo Brasileiro" (Brazilian chapter) and of the South American zone of the International College of Surgeons. Dr. Rudolph Nissen was elected president of the next congress, and among the future vice-presidents are the Brazilian surgeon Prof. Carlos Gama and Prof. Manuel Manzanolla from Mexico.

Ovarian Pregnancy.—A study on ovarian pregnancy was published by Drs. Domingos Delascio and Luidoso Credidio. They presented a complete historical review commencing with the De Sanctis Maurice case, which is considered to be the first recorded, in the year 1682. They recalled the work of Willigh, who insisted on the necessity for microscopic investigation for a diagnosis of the disease and the criticism of Lawson Tait about cases erroneously diagnosed. The English master referred to a case of a dermoidal tumor described as an ovarian pregnancy. The formulation of the four fundamental conditions for safe diagnosis of this ectopic implantation by Otto Spiegelberg in 1878 is mentioned. Drs. Delascio and Credidio record the study of Catherine van Tussembroeck, in the year 1899, in which, based on microscopic investigations, she was able to establish the diagnosis of ovarian pregnancy. The cause of ovarian pregnancy has been the object of much controversy. The authors believe that ovarian pregnancy may be caused by disturbance of two mechanisms: namely those of ovulation and implantation following pathological processes of the tubes and ovaries.

Cancer of the Esophagus.—A review of 82 cases of cancer of the esophagus and gastric cardia was presented by Prof. José Maria de Freitas and co-workers. The localization of tumor was as follows: interior third plus cardia, 46 cases; inferior third, 17; median third, 12; superior third, 3; and not specified, 4. The outstanding symptoms in these 82 cases consisted of: dysphagia, 69 times; vomiting and regurgitation, 57 times; pain at the inferior third of the retrosternal region, 52 times; and hemorrhage with hematemesis and melena, 10 times. All patients were noted to have lost weight, the loss being more than 10 kg. in the majority of cases.

X-ray examinations of the esophagus and stomach and endoscopic study of the esophagus, larynx, and bronchi are of the utmost importance for the diagnostic confirmation of cancer of the esophagus and cardia and the ultimate indication for surgical therapy. Good results were obtained through endotracheal anesthesia with total curarization, automatic respiration being controlled by the pulmotor; with surgical approach through left thoracotomy with resection of a rib; with esophageal-gastric or esophageal-jejunal anastomosis made with cotton sutures, far apart from each other, in two planes: those of the total inner layer being U-shaped and those of the external layer doubly anchored; systematic use of blood, about 500 cc. at each transfusion, alternating with saline, during the surgical proceedings; closed pleural drainage during 48 hours or more; esophageal-gastric intubation for 48 hours; and systematic use of penicillin and streptomycin locally and parenterally. Feeding is begun early, as soon as the 1st postoperative day, and consists of small amounts of liquid hourly until the 3rd day, reinforced with light foods the 10th postoperative day. Early passive and active exercise soon after the operation and early rising from bed, from the 3rd to the 5th postoperative day, are to be recommended.

The results obtained with surgical treatment (resection of esophagus and cardia) in 39 cases out of the 82 studied were as follows. Two patients who submitted to total resections of the esophagus lived through the immediate postoperative period, as did 19 of the 37 who submitted to transthoracic resection of the esophagus and cardia with immediate anastomosis. Among this same group, 18 died immediately. In the rest of the group, consisting of patients who underwent palliative operations, there were 18 deaths. Two patients died without having been operated on. Causes of death in 19 out of 39 patients who underwent resection were as follows: dehiscence of anastomosis 5, surgical shock 1, postoperative hemorrhage 3, cachexia 6, bronchopneumonia 2, and toxemia 1. The mortality rate tended to diminish in proportion to the speed with which the diagnosis was established and the rate that the authors' experience increased. Two patients underwent total resection of the esophagus six months and three years later, with cervical esophagostomy and gastrostomy, respectively. From those 19 patients who underwent radical operation, 2 persons lived two months, 1 lived three months, and 2 lived six months. This last one has been feeling well and is reasonably well nourished.

ECUADOR

Inquiry into the Health of Apparently Healthy Workers.—The Office of Ecuadorean Social Security, which is charged with giving medical care to private employees and workers, is studying the possibility of initiating services of preventive medicine. For this purpose, an inquiry was made in the city of Guayaquil, under the direction of Dr. Alfredo Valenzuela, into the health of 5,000 employees and workers. The results of this inquiry are interesting, since the employees and workers were apparently healthy.

Of the 5,000 persons examined, 3,317, or 66.34%, were men and 33.66%, women. Their ages varied between 20 and 50 years, but 66% were between 21 and 40 years of age. Seventy-six per cent were public and private employees, and 24% were factory workers. Of all these workers, 71% had a monthly income varying between 200 and 800 sucre, that is, $11 to $46, monthly; it should be noted that the cost of living in this country is somewhat less than that in the United States. Nevertheless, it is evident that the average monthly income is insufficient to satisfy even the most elementary needs.

Intestinal parasites were found in 62.84%, distributed as follows: Trichuris trichiura, 41.32%; Endamoeba coli, 21.08%; Ascaris lumbricoides, 11.68%; Trichomonas intestinalis, 7.60%; Ancylostoma duodenale, 6.36%; E. histolytica, 4.62%; Giardia lamblia, 3.74%; Taenia solium, 3.24%; Strongyloides stercoralis, 2.52%; Hymenolepis nana, 0.5%; with smaller percentages of Chilomastix mesnili, Balantidium coli, Oxyuris, Cercomonas, and Anguillula organisms. In 17.4% two or more of these parasites were found in the feces in association.

In regard to venereal diseases and syphilis, all the women in the inquiry denied ever having suffered such infections. Among the men, 19.54% stated that they had had gonorrhea, and 14%, chancre. Serologic tests in all those suspected and all those who

---

The items in these letters are contributed by regular correspondents in the various foreign countries.

had had any venereal infection were positive for syphilis in 8.6%, of whom 6.7% were men and 1.9% women.

There were 105 persons, or 2.1%, who proved to be tuberculous; of these, 48 showed slight tuberculosis, 41 moderately advanced tuberculosis, and 16 very advanced tuberculosis. Red blood cell counts between 3,800,000 and 4,200,000 were found in 76%, which indicated moderate anemia. In 11.24% the count was over 4,500,000 and in the remainder less than 3,700,000. Cardiac diseases had a low incidence: 0.88%, consisting, in most cases, of sinus tachycardia (0.36%). Similarly, there was a low incidence of renal diseases, amounting to a total of 0.83%.

Among the other diseases found, the principal ones were as follows: chronic constipation, 36.19% (22.10% in women); acute pharyngitis, 22.79% (women, 13.49%); tonsillitis, 22.21% (women, 15.80%); arterial hypertension, 10.58%; hernias (inguinal, umbilical, and epigastric), 5.49% (women, 2.66%); articular rheumatism, 5.27%; malaria, 3.9%; colitis, 2.76%; bronchial asthma, 2.44%; hepatitis, 2.27%; chronic bronchitis, 1.68%; varices, 1.58% (women, 1.55%); peptic ulcer, 1.28%; hemorrhoids, 0.69%; epilepsy, 0.06%; and cancer of the neck of the uterus, 0.06%. It is interesting to note the present low incidence of malaria, since the campaign carried on systematically throughout the coastal regions, contrasting notably with the figures of 5 or 10 years ago.

Tuberculosis in Azuay.—Under the direction of Dr. Agustín Landivar, the Ecuadorean Antituberculous League has carried out an investigation on the incidence of tuberculous infection and disease in the inhabitants of the central province of Azuay.

The investigation covered 10,734 persons, among whom 7,959 were found positive to the Mantoux test (40.95% with one plus; 37.25% with two; 13.3% with three, and 8.3% with four pluses). Of the total number, 4.66% were found to have active tuberculosis and 0.78%, inactive forms of tuberculosis.

The Rosenthal multipuncture technique was used in vaccinating 2,946 persons; tuberculin allergy and positive reaction to the Mantoux test were found to have been produced in 91.32%.

FINLAND

Bilberry Cure for Oxyuriasis.—The encouraging experiences of a three day bilberry cure for oxyuriasis at the Children's Hospital in Helsingfors are the outcome of observations of an isolated case. It was that of a 10-year-old boy who came to the outpatient department of the hospital suffering from diarrhea. He was told to eat bilberries for a couple of days. On his return to the hospital a fortnight later he had ceased to discharge pinworms (Enterobius vermicularis). This led to an extensive trial of bilberries as a cure for this condition by Dr. Bernhard Landtman of the Children's Hospital. The patients thus treated were 15 boys and 15 girls between the ages of 2 and 15 years. As many as 25 of them had been treated for oxyuriasis by various other means without success. From about half a liter to two liters of bilberries were eaten daily for three consecutive days, either as such or as a purée or thick soup. When fresh bilberries were not in season they were given in dried or preserved form. They were sweetened with sugar, and about a deciliter of milk was given daily with no restriction of the water intake. But no other food was permitted during these three days.

The success of this treatment depended largely on whether the child was treated in the hospital or at home. In the four cases in which the treatment had no effect the children had remained at home, and it is doubtful that the parents followed faithfully the instructions given them. Indeed, one mother admitted that she gave her child ordinary food on the second day of treatment for fear of starvation. In 18 cases the treatment was given in hospital or some other institution. In most of these cases there was an ample discharge of pinworms in the feces as early as the first day of the cure. As many as 20 patients were kept under observation for more than 3 months after the treatment, and the observation periods ranged from 14 days to 5 years. In none of the 26 successfully treated cases could pinworms be found within a few weeks of the completion of the cure, which seemed to be equally effective whether the bilberries were fresh or preserved. The two children who were found to have suffered a relapse nine months after the cure belonged to the same family and probably represented a new infection. No ill effects or complications were observed in connection with this treatment, which, in the opinion of Dr. Landtman, inhibited the development of the eggs of the pinworm as well as expelled the pinworm itself.

Tapeworm Pernicious Anemia.—The prevalence of the tapeworm in Finland has led to much research in this field, and at the Fourth Medical Clinic in Helsingfors, in the charge of Prof. Bertel von Bonsdorff, investigations have recently been carried out concerning the relationship of this parasite to anemia. Von Bonsdorff has shown that the tapeworm, when lodged in the upper sections of the small intestine, is able to prevent the interaction of the extrinsic and intrinsic factors involved in the development of tapeworm pernicious anemia. In cooperation with Dr. R. Gordin he has lately shown that the tapeworm itself absorbs these particular factors. Another investigation has been carried out at the University Hospital in Helsingfors by Dr. Gösta Björkenheim with special reference to the neurological sequels of the pernicious anemia caused by the tapeworm. During the period 1948-1950 he has carried out neurological examinations at various Finnish hospitals of 95 patients between the ages of 11 and 75 who were suffering from this particular form of pernicious anemia. In as many as 75 of these cases there was evidence of some degenerative process in the nervous system.

A close study of these cases showed that in 34 of them the involvement of the nervous system was severe enough to impair capacity for work, the chief cause of this incapacity being ataxia. A reexamination of 80 of these patients from 1 month to 24 months after vermifuge treatment showed that the blood picture had usually become satisfactory. The condition of the nervous system had become worse only in six patients, while the remainder showed improvement or complete recovery. Indeed, the improvement had been so marked in more than half these cases that a neurological examination revealed nothing amiss. In the opinion of Dr. Björkenheim, this satisfactory response to vermifuge treatment depends on the restored ability of the human organism to make proper use of the essential factors in question. The observation that some lesions of the central nervous system are reversible in cases of tapeworm pernicious anemia must, however, be qualified by the admission that certain of these lesions are permanent. Dr. Björkenheim has found that liver preparations and vitamin B_{12} exert a beneficial influence on these neurological manifestations but not more so than vermifuge treatment alone.

Study of Congenital Syphilis.—At the Haga Welander Home for children suffering from congenital syphilis, Dr. Ole Enkvist of Helsingfors has investigated the problem of whether specific treatment of a syphilitic mother during pregnancy affects the prognosis of her offspring. It has been argued that so-called malignant cases of congenital syphilis, refractory to specific treatment, occur as frequently among the children born to mothers given specific treatment during their pregnancy as among the children for whom no specific prenatal treatment has been given. Dr. Enkvist's material concerns 555 children who suffered from congenital syphilis, who were less than 3 years old, and who could be classified in two groups according to whether their mothers had received specific treatment with bismuth and arsphenamine during their pregnancies. In the first group there were 102 children, and in the second 453.

A comparison of 61 children in the first group with 131 in the second with reference to the date at which the first signs of congenital syphilis appeared showed that there was no appreciable difference in this respect between the two groups. But when they were compared with regard to weights at birth, it was found that the group with untreated mothers was considerably lighter in weight. The mortality among the 102 children in the first group was 26%, whereas among the 453 children in the second group it was as high as 36%. Yet another comparison showed that the number of uncomplicated and relatively mild lesions predominated in the first group, whereas visceral syphilis with a definitely and persistently palpable spleen was commoner in the second group. Syphilis of the bony system was also more frequent in the second group. On the other hand, neurosyphilis was more frequent in the first group, and this observation is in conformity with the well-established finding that the neurosyphilis of adults occurs more frequently among patients given inadequate treatment than among others given no treatment at all.

Dr. Enkvist concludes that, though specific treatment of the mother during pregnancy may better the prognosis for her syphilitic offspring, the benefits obtained are not as great as expected. The number of the patients in his first group is rather small for a statistical analysis such as this, and it is further impaired, as he points out, by the lack of sufficiently exact data with regard to the treatment each of the expectant mothers received.

ITALY

Medicosurgical Society.—The medicosurgical society of the Romagna region held a meeting on Feb. 10, under the chairmanship of Professor Sighinolfi. Professor Musconi, from Imola, reported two cases of echinococcus cysts of the liver in which clinical, radiological, and laboratory findings led to a wrong diagnosis that could not be rectified during the surgical intervention because the complications that occurred within the cysts (hemorrhagic overflowing in one case and biliary infarction in the other) had greatly altered their anatomic and pathological characteristics. In the first patient the surgical intervention was performed for gastric ulcer and a blood cyst of the liver was found. One year later during a second intervention in the same patient multiple echinococcus cysts were found, one of which was located in the lumen of the common bile duct. In the second patient a large mass beneath the liver was diagnosed clinically as dropsy of the gallbladder, since all symptoms of echinococcus infection were absent and cysts of the gallbladder were not revealed by the roentgenograms. During the operation the cyst was not found; histological examination justified diagnosis of echinococcus cyst. Professor Musconi concluded that diagnosis of echinococcus cyst is very difficult and sometimes impossible in cases of dead cysts in which all clinical symptoms are absent.

Professor Santini, from Ravenna, discussed radiological diagnosis of gastric ulcer. If the anatomic and pathological statistics are compared with the clinical and radiological, it is seen that diagnosis of gastric ulcer is not thought of often considering the frequency of this lesion. Of particular interest in the statistical study is the ratio between the frequencies of gastric ulcer and duodenal ulcer: in this field the disagreement between clinical pathologists and anatomic pathologists is pronounced in that the former support a more frequent occurrence of duodenal ulcers, the latter of gastric ulcers. Discussing the diagnosis of gastric ulcer, Professor Santini pointed out that in about half of the cases classic symptoms permitting a diagnosis based only on anamnestic study are not present. Radiological examination is superior to clinical examination, but many times a gastric ulcer also escapes the radiologist.

The only radiological pathognomonic sign of the gastric lesion is the niche, but indirect signs, such as antral gastritis, incisura of the great curve caused by spasm of the gastric muscles, retraction of the small curve, eccentricity of the pylorus compared with the base of the duodenal bulb, the deviation toward left of the duodenal bulb, and segmentary rigidity, are also valuable. Several technical devices may be used to put in evidence signs of ulcer; in order for the niche to become visible it is necessary that the bright bundle of rays be perpendicular to the diametrical plane of the gastric cylinder passing through the niche. The study of the patient in standing, inclined, and right triclinic position may be advantageous in each particular case. Therefore, Professor Santini concluded that it is impossible to recommend a standard position, but each position should be used according to the zone that is being studied and to the constitutional configuration of the stomach. Trendelenburg's position should not be excluded since it is very useful in those cases in which the cephalic pole of the stomach is being studied. This zone is often overlooked.

Comparing the advantages that may be obtained by means of an examination with small doses and large doses of opaque medium, he observed that the former is useful for revealing modifications of the folds of the mucous membranes but is almost always insufficient to reveal an ulcerous niche. Large doses of opaque medium can penetrate in the ulcerous excavation provided that the level of the meal reaches the ulcer. When it is believed that the ulcer is located in a high position, a second meal of barium may be given, or else the patient may be forced to a voluntary abdominal retraction while the radiographs are taken. By these means ulcers of the superior tract of the small curve are often detected that otherwise would not have been seen.

This technique in examining the digestive tract has been followed for many years at the radiological department of the Ravenna Hospital where about 5,000 patients have been examined from January, 1948, to July, 1950. The results reveal that the number of gastric ulcers is greater than that reported by clinical physicians and also by some radiologists and that, therefore, the ratio between the occurrence of duodenal ulcer and gastric ulcer is smaller than that usually thought of.

Drs. Suzzi Valli and Dominici reported on the first case of autochthonous visceral leishmaniasis that occurred in the Romagna region in 1951 in an adult living in a locality of the Forlì province. The Romagna region is the source of endemic centers of cutaneous leishmaniasis from which the disease is progressively spreading, but up to date no case of the visceral form had been reported.

SWEDEN

New Light on Rickets.—The tendency of modern textbooks to oversimplify the etiology of rickets by tracing this disease solely to the lack of sunlight and vitamin D is challenged by Dr. Gert V. Sydow, who presents an analysis of 64 cases of active rickets observed during a four year period at a hospital in Sundsvall since its children's department was opened in September, 1947. In addition to the 64 active cases there were 14 in which the disease had been arrested. This analysis, published in *Svenska Läkartidningen* for April 10, 1952, shows that there were 21 girls and 43 boys suffering from active rickets. The average age of the girls was much higher than that of the boys when rickets was first diagnosed; before the age of 10 months there were only 3 girls as compared with 31 boys. On the other hand, among the 13 cases of rickets diagnosed after the age of 12 months, there were as many as 8 girls. There was also a sex difference with regard to the incidence of tetany, which affected 21 infants, 17 of whom were boys. Dr. V. Sydow suggests that these sex peculiarities, if confirmed by a larger series and statistical analysis, indicate a genetically determined element in the etiology of rickets. His material also includes cases indicating a hereditary and familial element in the etiology of the disease. Another observation is that the persons with rickets are undersized, a condition again suggesting a congenital factor of a genotypic nature. Dr. V. Sydow is unable to confirm the theory that rickets is a function of growth and that the risk of developing rickets increases with the rate of growth of the child. It should be noted that his diagnosis of rickets depended on radiological examinations of the wrists and on serum analyses.

Alcohol and Venereal Disease.—The committee appointed under government auspices to investigate problems concerned with the control of alcohol in Sweden has made a special study of the connection between alcohol and venereal disease. In cooperation with the public health service, it issued a detailed questionnaire to patients receiving treatment for venereal disease in venereal disease centers and from medical officers of health and private practitioners. The recipients of this questionnaire were asked to fill in data concerning their sex, age, occupation, the date when infection occurred, and the place in which infection occurred, i. e., in a hotel, a cellar, a passage, or out of doors. Further, they were to tell whether there was a permanent or a casual relationship with the partner, and, if the latter, whether it was for payment. Many other points were raised, such as the character of the places of entertainment in which the partners had met, whether appointments had been made by telephone, and whether the partner was a fellow citizen or a foreigner. They were asked whether one or both partners were under the influence of alcohol at the time and in what form it had been consumed. The veracity with which the questionnaire was answered may have varied somewhat with the sex and occupation of the recipient. For example, the women were apt to be inaccurate over the character of their partnerships, not liking to be classed as prostitutes. As many as 1,413 questionnaires were answered well enough to be suitable for statistical study. Infections received on Saturdays and Sundays were together more numerous than the infections received during all the rest of the week. More than 60% of the men had been infected by casual or occasional partners. This was so for barely 15% of the women; most of the others were infected by more or less permanent partners. Not one woman considered herself a prostitute. Nearly half of the seamen were infected by prostitutes. About four-fifths of the men infected through prostitution were under the influence of alcohol at the time. During casual relationships, more than half of the men were under the influence of alcohol, and 42% of the women with casual partners consumed alcohol at the time. Patients infected abroad more often were under the influence of alcohol at the time than patients infected in Sweden. It was remarkable that the infection rate was so high in places of entertainment in which no alcohol was served. The 15 pages devoted to this discussion contain many tables and diagrams from which the reader can glean information without drawing any cut and dried conclusions as to the exact share taken by alcohol in promoting venereal disease.

Refusal of Physician to Induce Legal Abortions.—Trouble has lately risen over the refusal of a professor in the gynecologic department of the Sabbatsberg Hospital to induce abortions authorized as legally permissible by the authorities. The matter has been given so much prominence in the lay press that the Swedish Medical Association has felt obliged to publish a memorandum on it. It pointed out that it is the duty of every physician to give the advice and treatment that his patient's condition requires and that is in conformity with scientific knowledge and well-tried experience. He may be held responsible when he ignores these considerations, but no Swedish law obliges a physician to carry out any operation on human beings. Legislation provides for the induction of abortion but does not oblige a physician to induce it when he finds abortion unjustifiable. To threaten such a physician with penalties and dismissal from his post for this reason would be to abandon the principles governing the practice of medicine in the Western world. "It is in dictator states that doctors are obliged in the exercise of their profession to act contrary to their scientific and ethical convictions." It is pointed out in this memorandum that the Swedish Medical Association is concerned only with the principles involved and not with any individual case still before the court.

Prophylaxis of Acoustic Trauma.—In the ear department of the Falun Hospital, Dr. Rolf A. Hillesund has compared the effects of various devices for the prevention of acoustic trauma. With the help of audiograms he noted the protective effects of vulcanite earplugs, ordinary cotton wool, and glass fiber wool on 10 persons with normal tympanums. Vulcanite earplugs are not, in his opinion, bearable as a rule for more than a couple of hours in the day, and they seldom fit well. On the other hand, glass fiber wool can be made to fit well in every case, can be used all day with greater comfort than the vulcanite plug, and is quite cheap. With glass fiber wool in both ears, persons with normal hearing can usually catch a speaking voice several meters away. Dr. Hillesund believes that there is little chance of glass fiber wool provoking eczema in the auditory passages. Referring to the problem of acoustic trauma in general, he pointed out that at the present time the best prophylactic measure seems to be the protection of the individual user rather than the provision of machinery for silencing sounds.

The Influence of Climate on Rickets.—At a meeting of the Swedish Medical Society, several speakers dealt with the diagnosis of rickets by radiological examinations. As these are not always available, clinical criteria become more important than ever, and one speaker referred to craniotabes as the most objective physical test or sign of rickets. The same speaker, Dr. Sixten Haraldson, showed what a profound influence climatic conditions in the north of Sweden can have on rickets. The grotesque skeletal deformities portrayed in the textbooks may be rare, but he has seen a score of cases of craniotabes every year at Kiruna, in the far north of Sweden. After the sunless summer of 1949 there were some three score such cases seen. In the far north much of the penetrating effect of the solar rays is lost, and this loss is not sufficiently compensated for by reflection from the snow or by freedom from industrial pollution of the air. The comparatively sunny months of March and April usually have such low temperatures that little of a child's skin can be safely exposed to sunlight out of doors. The midnight sun in the summer is of course not available for the child who is dutifully sent to bed at night. The sunlight of July and August is often wasted because swarms of mosquitoes often render life out of doors quite unbearable. Dr. Haraldson declared rickets to be one of the causes of the defective teeth and delayed dentition often observed in Kiruna. He was in favor of fish-liver oil as a prophylactic, to be administered with special reference to the climatic conditions in the north of Sweden.

SWITZERLAND

Inquiry on Prefrontal Leukotomy.—The periodical *Médecine et Hygiène*, a Swiss medical journal published fortnightly in Geneva, sent a questionnaire to specialists in psychosurgery from America, France, and Switzerland asking them to express their opinions concerning the indications and contraindications of this therapy, the damage it caused to personality, and the medicosurgical problems it entailed. Answers favorable to prefrontal leukotomy included those from Dr. Freeman, professor at the Psychiatric Institute of Washington, who compared psychosurgery to any other surgical operation devoted to alleviating suffering; from Dr. Wertheimer, professor of neurosurgical clinics at the Faculty of Medicine of Lyons (France), who estimated that leukotomy is an efficient therapeutic act in many cases; and from Professor Lhermitte (Paris), Dr. Bersot (Switzerland), secretary of the European Federation for Mental Health, Dr. Cossa (Nice), and Dr. Feuillet (Nancy) who think that frontal leukotomy is the only medical act capable of opening a way of hope to patients who had before an intolerable life.

Professor Morel, head of the university psychiatric clinic of Geneva, and Dr. Baruk, chief of the clinic of Charenton (Paris), were opposed to leukotomy. The former, founding his opinion on histological facts, estimated that the enormous quantity of fibers cut by the surgical section must provoke the secondary degeneration of the cortical neurons afferent to the sectioned fibers; this opinion is not accepted by Wertheimer, who thinks that there is no degeneration, because of the short fibers of association. Baruk considers that leukotomy results in serious damage to the moral personality of schizophrenic patients and would like to see this operation abolished. Other persons, like Dr. Porot (Alger), admit leukotomy but make reservations for its indications.

Opinion was unanimous that leukotomy should be done only after all other treatment has failed. Leukotomy is indicated only in cases having no tendency to spontaneous healing and showing a behavior that is not compatible with any social life or that is dangerous for the patient (suicide).

Most of the authors, even those who are opposed to leukotomy, do not place much emphasis on the postoperative problems of behavior; if the characteristics change, they change in a favorable rather than an unfavorable way.

Concerning the medicolegal aspect, all believed that the decision must be made by the psychiatrist, but with the agreement, if not of the patient, at least of his family or guardian. The legal responsibility of the patient who has undergone leukotomy varies according to his state of mind, established by a survey, as in any other litigious case.

On the whole, in viewing the gravity of the cases undergoing leukotomy, favorable results, even of modest percentage, though they sometimes reach 20 to 30% of schizophrenias (Wertheimer), must be taken in consideration. In the absence of more effective therapy it would not be wise to recommend abolition of prefrontal leukotomy, even if it is yet only a palliative process.

POTENTIAL DANGER OF ISONIAZID RESISTANCE THROUGH FAILURE TO USE MULTIPLE CHEMOTHERAPY IN TREATMENT OF TUBERCULOSIS

To the Editor:—Not since the advent of streptomycin has the medical profession been given an antituberculosis drug with the tremendous therapeutic potentialities of isoniazid. Are these potentialities to be fulfilled, or is isoniazid to become rapidly ineffective owing to the development of bacterial resistance? The answer to this urgent question depends on the attitude of those responsible for its clinical use. Most physicians are already aware of the dangers inherent in the development of isoniazid resistance, but, if a minority is to take the position that bacterial resistance is a laboratory curiosity of no clinical significance, the value of this drug may be greatly lessened. It is a matter of historical record that the wide use of sulfadiazine in naval training centers during World War II eventually resulted in the establishment of streptococcic types resistant to sulfonamides (Epidemiology Unit no. 22: *J. A. M. A.* **129**:921-927 [Dec. 1] 1945). This unfortunate experience in the administration of drugs to relatively segregated groups appears to have been largely forgotten.

While it is true that bacterial resistance to penicillin and sulfonamides in our civilian population has not yet presented serious difficulties, two facts about isoniazid in the treatment of tuberculosis set it apart as a special problem. First, it is significant that patients in tuberculosis hospitals represent segregated groups; furthermore, they have a more or less active chronic disease. Infection with isoniazid resistant strains of extraneous origin may be expected in some hospitals and, later, in the general population. The euphoria and subjective improvement of patients treated with isoniazid will make their control all the more difficult, and the narrow antibacterial specificity of isoniazid will leave secondary infection relatively unchanged.

The second important fact is that isoniazid is the only commercially available chemotherapeutic agent known, other than streptomycin, against which bacteria can develop practically complete resistance in a single step (Szybalski, W., and Bryson, V.: *Am. Rev. Tuberc.* **65**:768-770, 1952). Although this evidence is based on a study of nonpathogenic tubercle bacilli, it has been indicated that human pathogens behave similarly in the development of isoniazid resistance (Middlebrook, G.: *Am. Rev. Tuberc.* **65**:765-767, 1952; Hobby, G., and Lenert, T. F.: *ibid,* **65**:771-774, 1952). Unlike levels of bacterial resistance, the pattern depends on the drug rather than on the species of bacteria (Demerec, M.: *J. Bact.* **56**:63-74, 1948; Bryson, V., and Demerec, M.: *Ann. New York Acad. Sc.* **53**:283-289, 1950). Also, resistance to isoniazid orginates about 1,000 times as rapidly as streptomycin resistance. In terms of mutation rate, an isoniazid resistant bacterial cell will arise on the average in bacterial populations 1,000 times smaller than are required to produce streptomycin resistance. For those who still believe the origin of resistance by mutation rather than by drug contact is an academic hypothesis, the simple isolation of fully isoniazid resistant strains in the complete absence of the drug by the replicate plate method of Lederberg should remove the last vestige of doubt (Szybalski, W., and Bryson, V.: unpublished data). Although reversion to sensitivity through more rapid growth of sensitive mutants may occur in the laboratory following removal of isoniazid from the media, many bacterial generations are required, and there is no assurance that similar reversion will occur in vivo.

In the recent meeting of the National Tuberculosis Association at Boston (May 26-29, 1952) it was reported by attending physicians that extensive tests of isoniazid are in progress or are soon to be made. A few of these tests will contrast the effects of isoniazid used alone against other forms of chemotherapy. This we regard as nothing short of catastrophic. Isoniazid resistant strains of human tubercle bacilli following relatively brief therapy have already been reported by Steenken, Meade, Wolinsky, and Coates (*J. A. M. A.* **149**:187 [May 10] 1952).

When first available, streptomycin was also used alone. The necessity of administering *p*-aminosalicylic acid with streptomycin to retard the origin of resistant strains was learned as a result of much time and effort. When bacterial resistance is a problem, the advantages of using multiple chemotherapy have often been stressed (Carpenter, Bahn, Ackerman, and Stokinger: *Proc. Soc. Exper. Biol. & Med.* **60**:168-171, 1945; Grace, E. J., and Bryson, V.: *Arch. Surg.* **50**:219-222 [April] 1945; Bryson, V., and Grace, E. J.: *New England J. Med.* **237**:683-692, 1947; Klein, M., and Kimmelman, L. J.: *J. Bact.* **54**:363-370, 1947). Mutation to resistance against two drugs used together is theoretically the product of individual mutation rates. In the case of isoniazid and streptomycin combined, a volume of bacteria almost as great as the entire human body would be required for the finding of a cell simultaneously resistant to both agents. On the other hand, the use of drugs in sequence, as resistance develops to each in turn, will not prevent the eventual occurrence of multiple bacterial resistance. If the organisms of human tuberculosis develop very high isoniazid resistance by a single step mutation, no clinically feasible dose of the drug used alone will prevent the selection of resistant strains, providing the bacterial population is moderately large or actively multiplying.

There is no doubt that large-scale tests of isoniazid by hospitals and physicians engaged in private practice will soon begin. In spite of some antagonism of isoniazid with subinhibitory concentrations of streptomycin (Szybalski, W., and Bryson, V.: unpublished data), we suggest most emphatically that isoniazid be employed only in multiple combinations with streptomycin and *p*-aminosalicylic acid or other chemotherapeutic agents active against mycobacteria and not related by cross resistance. For example, streptomycin-*p*-aminosalicylic acid therapy should be compared with and without isoniazid, rather than as an alternative to isoniazid. Otherwise, we predict the early and widespread appearance of isoniazid resistant strains of tubercle bacilli. Such an event will largely neutralize one of the most hopeful developments in the recent history of tuberculosis therapy.

In releasing isoniazid to the medical profession the Food [illegible] Drug Administration has approved package labels stating [illegible] use in the treatment of streptomycin resistant tuberculosis [illegible] close supervision of a physician." While the treated [illegible] temporarily improve with isoniazid, the eventual [illegible] others with organisms resistant to both streptomycin [illegible] azid could make any prolonged medical program [illegible] F. D. A. recommendations a potential threat [illegible] value of the drug. We would prefer to see [illegible] use only in combination with another tu[illegible] tive against tubercle bacilli of the patient [illegible] be between prolonging the lives of a few [illegible] today as opposed to controlling tuber[illegible] within one generation.

POLLEN PREVALENCE AND POLLEN-FREE AREAS

To the Editor:—In the correspondence section of THE JOURNAL May 3, 1952, page 82, Dr. Ralph Bookman of Los Angeles voices his concern about the effect on the average physician of my article "Pollen Prevalence and Pollen-Free Areas," which appeared in THE JOURNAL March 1, 1952, page 716. He is also disturbed by the economic and social dislocation which he predicts for many of those pollen sensitive persons "who heed such advice." If this were the first appearance in medical and lay publications of the facts about quantitative pollen distribution, one might be persuaded to share the doctor's pessimism, since no one denies that facts, unless interpreted with common sense, are often dangerous. But the article in question has only augmented a body of similar observations published in numerous medical journals and books over a period of 25 years by many allergists as well as by their collaborators.

It seems pointless to deny that a pollen sufferer may ever escape pollen allergy by avoidance of the pollens to which he is sensitive. This is the only conclusion to be drawn from Dr. Bookman's effort to brand as fallacies first "that it is possible to escape a pollen allergy, and, second, that there are certain areas, suggested by the accompanying maps, to which a pollen sensitive person may flee." In this he does not agree with the teaching of his fellow allergists or take into account the satisfactory experience of many ragweed sensitive patients. Dr. Morrill Wyman, as early as 1876, recorded cases of ragweed allergy in which the sufferer obtained perfect relief for a whole season by going to Europe or to the wooded areas of Canada during August and September. Tuft, in "Clinical Allergy" (Philadelphia, Lea & Febiger, 1949) says, "Complete elimination of the offending allergen from the diet or environment of the patient is the ideal therapeutic method, since it obviates the necessity of other treatment." Feinberg, in "Allergy in Practice" (Chicago, Year Book Publishers, 1946) says, "The ragweed-sensitive patient may be relieved by living in European countries, Asia, parts of South America, Africa, and Australia—no matter what the climate may be. The ragweed-sensitive patient may find increasing relief the farther north he goes into Canada or by going west of the Rockies or to the southernmost portion of Florida. Persons sensitive to certain other pollens may come to the Midwest with consequent relief." Alexander, in "Synopsis of Allergy" (St. Louis, C. V. Mosby Co., 1947) says, "The ideal treatment of hay fever, like other forms of allergy, is to avoid contact with the offending agent. . . . The availability of pollen counts over several years in essentially all sections of the country offers an excellent guide as to where one may go to escape hay fever."

As for Dr. Bookman's statement that "A person sensitized to eastern pollen who moves to this area will probably become sensitized to our local flora within a period of from 6-18 months," the possibility that ragweed sufferers from the middle and eastern states may in time become sensitized to indigenous California pollens has already been discussed in considerable detail by southern California allergists, as well as by those having clinical experience both in the ragweed belt and in southern California (*J. A. M. A.* **139**:554 [Feb. 19] 1949; ibid. **141**:99 [Sept. 3] 1949). Due attention has also been given to the matter in my chapter in Vaughan's "Practice of Allergy," second edition (St. Louis, C. V. Mosby Co., 1948, p. 470). Suffice it to say that there are no published data available on the frequency with which such new sensitization may occur, so that it is not possible to evaluate Dr. Bookman's use of the term "probably" in this connection. It is, however, pertinent to inquire: How many of those who do change residence without any subsequent difficulty take the trouble to report such a happy outcome to any allergist in the new locality?

ULTRAFILTRABLE ACTH ACTIVITY OF HUMAN PLASMA

To the Editor:—We have previously published in THE JOURNAL (**147**:525 [Sept. 29] 1951) a paper concerning the adrenocorticotropic activity of human blood, directly testing the plasma with the "ascorbic acid depletion method," according to our own technique. In our paper we called attention to the fact that in comparative experiments losses of adrenocorticotropic activity might occur when the determination is made with fractionated plasma (Bornstein and Trewhella, *Lancet* **2**:678, 1950) since the blood fraction with adrenocorticotropin activity is not totally precipitated from +94% acetone.

Our observations and some reports of other authors that the biologic activity of corticotropin (molecular weight 20,000) is not connected with the intact protein molecule but with one of its fractions (Li, C. H.: *Nederl. tijdschr. geneesk.* **94**:1093, 1950) have induced us to investigate whether the corticotropic hormone is, also in the blood, in a form simple enough to be ultrafiltered.

Until now, studies have been performed on blood of five normal adults. The plasma of every person was tested comparatively, before and after ultrafiltration, with the ascorbic acid depletion method. The volume injected in each animal subjected to hypophysectomy was in every case 0.5 cc. per 100 gm. of body weight. Three animals were used for each experiment.

The plasma ultrafiltration was performed immediately, with a cellophane membrane in an adequate ultrafilter, at a pressure of 15 atmospheres, in inert gas (nitrogen) and at a temperature of +2 C. In 90 minutes it is possible to obtain a volume of ultrafiltrate sufficient to make injections in three animals.

Mean falls in ascorbic acid concentration of adrenals expressed as milligrams per 100 gm. of fresh tissue, according to our experimental conditions, were 35.6±3.6 mg. for the plasma before and 46.6±4.25 after ultrafiltration.

From these results, we conclude that the adrenocorticotropic activity of the blood of normal adults is completely ultrafiltrable. Further results on this subject will be published more extensively in another paper.

CHOLINERGIC DRUGS IN PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIA

To the Editor:—An article entitled "Use of Cholinergic Drugs in Paroxysmal Supraventricular Tachycardia," by Furman and Geiger (*J. A. M. A.* **149**:269 [May 17] 1952) has come to our attention. In the "comment" section of the article by Drs. Furman and Geiger, we note the following statement: "In our opinion, neither agent should be used in the average case except after less dangerous methods have been properly employed without success." Using the word "neither" implies condemnation of both, either individually or in combination. From the studies reported in this paper it is obvious that such a statement indicting either drug independently is not warranted, especially since both had been used in each instance. In the last sentence of the same paragraph we find the statement: "Only in such situations in which the patient's condition is so grave . . . do we feel that the use of methacholine is justified." With the primary attention focused repeatedly on methacholine, neostigmine is still mentioned as an accessory drug of hazardous action.

The undersigned independently introduced the use of neostigmine for paroxysmal tachycardia in clinical medicine in 1941 (*M. Rec.* **153**:134 [Feb. 19] 1941; ibid. **153**:209 [March 19] 1941). In our experience of over 1,000 injections of neostigmine, many of these for supraventricular tachycardia of sinus, auricular, or nodal origin, we have yet to witness a severe reaction due to its use. We still recommend the use of neostigmine methylsulfate, 1 mg. subcutaneously, in the management of paroxysmal supraventricular tachycardia.

COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

The Council on Medical Education and Hospitals has adopted the following statement and voted that it be published.

DONALD G. ANDERSON, M.D., *Secretary.*

FULL COST TUITION

The problem of financing the medical schools, always a difficult one, has been intensified since the end of World War II. To meet this problem, a number of schools have recently considered raising tuition charges to meet or nearly meet the full operating costs involved in the instruction of undergraduate medical students. In support of such action, it is argued that the average medical student will some day receive a comfortable income and that it is reasonable to ask him to pay the entire cost of his education. Several varieties of payment plans with varying exemptions have been suggested, but all are based on essentially the same principle, which is that the medical student, on entering medical school, signs an unsecured note for the difference between the usual tuition fee and the "full cost" to the school of his education, the amount to be repaid over a long period following his entrance into active, private practice. These plans are offered as new and perhaps "revolutionary" innovations in medical school financing. Actually, there is nothing new or unique about them except the techniques of collection.

The principle of full cost tuition is as old as American medical education and was discredited more than 40 years ago. Most of the arguments that may be advanced to support it today were given expression by the proprietary medical schools when an earlier generation of American medical educators stated their conviction that a stable high grade program of medical education could not be financed primarily by student fees. In 1910 Abraham Flexner wrote: "Our conclusion is that established schools . . . may count on fees to the extent of one-third to one-half of the expenditure required to conduct a good school of modern medicine; and that as the department becomes more homogeneously developed, the fees will tend to do even less."

Although the plans referred to assume that a medical school can compute accurately the full cost of educating a medical student, several recent studies have indicated that it is extremely difficult if not impossible for most medical schools to segregate the basic cost of medical instruction from costs incurred in the instruction of other students, in research, and in medical care. Until such figures can be derived, the fairness of any charge that purports to represent the full cost of medical instruction would be open to serious question.

It must be clear that all these plans would be subject to the same dangers and abuses that were inherent in the proprietary schools. It is not unforeseeable that a medical school operating under such a program would be strongly tempted to solve certain of its faculty problems by the simple expedient of raising salaries at student expense. Furthermore, it is but a short step from use of student fees to maintain essential teaching laboratories to the exploitation of such fees for the acquisition of special equipment, for maintaining research, and for the remodeling or even the construction of new facilities. If some of these fears seem farfetched it need only be recalled that they are the very abuses that the leaders of American medicine were struggling but a few years ago to eliminate.

It may be granted that full cost charges would temporarily ease the financial burden of the schools. It is probable, however, that such charges would in time actually make the situation worse. It would mean the abandonment of the established principle that medical education is a social function and is, therefore, rightfully a public trust. Years of effort have been expended in enlisting the interest, sympathy, and support of the general public for medical education, and the splendid development already achieved by the nation's medical schools is a measure of the public's willingness to bear this responsibility. It is entirely possible that placing the whole burden of operating costs on the student might jeopardize or even eliminate other important sources of support by appearing to reduce or to remove the need for support from such sources. Irrespective of the reasons offered in support of such a plan, many will regard the institution of full cost tuition as an abdication of social responsibility by the governing boards of universities.

One of the most serious objections to full cost charges concerns their possible effects on the schools adopting such policies and on the student himself. It is unlikely that a student will either pay these large fees or obligate himself to pay them on long-term contract if he can gain admission to an equally good school at less cost. The full cost school would then be placed at a serious disadvantage in the competition for able students and might easily find itself largely a school of last choice. It is equally possible that many students would choose other careers rather than assume such a long-term financial obligation. The study of medicine would then be left largely to the well-to-do, who could afford outright payment, and medicine would lose the services of many able and deserving persons.

The consequences to the ideals and ethics of medical practice that might follow the practice of putting such a high price on medical education would be most serious. At present, although students of medicine are aware of the financial sacrifice that they make through spending long years in training while their contemporaries are already gainfully employed, they are also aware that others are contributing significantly toward the cost of their education. It is impressed on a student that, while the physician is ordinarily entitled to payment for his services, remuneration must not be the primary consideration on which rendition of service is based. Altruism and compassion are paramount elements and are traditionally considered to be the vital, motivating forces in medical practice. As soon as medical education is placed on a dollar for dollar basis, with a large price attached, those ideals are placed in jeopardy. The graduate, laboring under a large debt, would be sorely tempted to regard his practice as a business enterprise, purchased in the market place, to be exploited and commercialized accordingly.

In view of all these inherent and potential dangers, the Council on Medical Education and Hospitals believes that plans for charging full cost tuition should be condemned as being inimical to the best interests of medical education and the public.[1] It would appear that the future quality of medical schools and of the practice of medicine will be better safeguarded if the medical schools will continue to cultivate and expand accepted sources of support. Recent developments would seem to indicate that there is no need for despair and that, as there is developed an increasing awareness of the social functions and benefits provided by their medical schools, increased support from the general public may be anticipated.

---

[1] The Council distinguishes between plans charging the individual medical student the full cost of his education and plans such as those developed by regional educational programs by which a medical school in one state receives from a governmental agency of another state a subsidy, which may be in the form of a full cost tuition charge, for each student it admits from the latter state. Such a program represents essentially the purchase of services by one state from another state and is not subject to the abuses or undesirable effects that would result from charging the individual student for the full cost of his education.

BUREAU OF MEDICAL ECONOMIC RESEARCH

THE REVISED KEOGH-REED BILLS

(H. R. 8390 and H. R. 8391)

Frank G. Dickinson, Ph.D.

The original bipartisan Keogh-Reed bills (H. R. 4371 and H. R. 4373) were introduced into the House of Representatives on June 7, 1951, at the request of the Special Committee on Retirement Benefits for Lawyers of the American Bar Association. The chairman of the committee is Mr. George Roberts, 40 Wall Street, New York City, and the draftsman of the identical bills was Mr. Leslie R. Rapp, a lawyer of New York City. Late in 1951 Mr. Roberts organized a Co-ordinating Committee on Retirement Benefits for the Professions and the Self-employed and has served as its chairman. This committee is composed of representatives of more than a score of organizations—mostly professional—and of the American Farm Bureau Federation. The representative of the American Medical Association is the Director of the Bureau of Medical Economic Research.

The original Keogh-Reed bills have been studied in great detail by the representatives of many national organizations. Several conferences were held with the technical staff of the Joint Committee on Internal Revenue Taxation of Congress. The revised drafts of these identical bills were introduced on June 27, 1952, by Representatives Eugene Keogh (D, N. Y.) and Daniel Reed (R, N. Y.). (In order for a bill in the House of Representatives to be truly bipartisan, two identical bills must be introduced, one by a Democratic Congressman and the other by a Republican Congressman.) They were referred to the Committee on Ways and Means on June 27, but the committee took no action on them before Congress adjourned on July 7. The bills will be introduced again next January. The revised bills (H. R. 8390 by Mr. Keogh and H. R. 8391 by Mr. Reed) resulted directly from the hearing of May 13 by the Committee on Ways and Means of the House of Representatives.[1] At that hearing, a number of amendments and changes were suggested by some of the 19 persons who testified. In the revised draft an attempt was made to follow as many of the suggestions made during the hearing as seemed to be in the public interest.

The general purpose of this bill is to provide a voluntary pension system for self-employed taxpayers who cannot be covered under the terms of section 165 (a) of the Federal Internal Revenue Code and to cover employed persons who for one reason or another are not covered and cannot expect to receive a pension from their employer. In other words, the purpose of this revised measure is to bring about a degree of equity for the taxpayers who are not now covered by pension plans with those who are now covered by pension plans approved under section 165 (a), by pension plans of local, state, and federal units of government, or by plans of nonprofit organizations. It is imperative that the federal internal revenue law cease to discriminate against certain taxpayers in the matter of pensions.

This discussion is not concerned with the Social Security Act, which for the present purposes may be considered the first layer of pensions; rather it is concerned with the second layer of pensions, in which the employer and employee, by a wide variety of plans, seek to provide pensions for the employees to be financed by premiums paid to insurance companies or by amounts set aside in pension and profit sharing trusts. More than 16,000 pension plans have been approved under section 165 (a) since it was enacted in 1942. Ten million of the 60 million gainfully employed are currently outside the scope of this section because they are self-employed. But the self-employed, as they grow older, are just as much subject to the feebleness and vicissitudes of old age as those who during the working years were employed persons covered by employee-employer pensions.

Before the differences between the old and the new versions of this measure are explained, certain basic facts should be set forth. Although it has not been possible to obtain any data from the pension trust section of the Bureau of Internal Revenue, available estimates indicate that several billion dollars paid by employers into a variety of pension plan funds are not currently being taxed to either the employer or the employee, although the employee when he retires will be required to declare as taxable income that portion of his pension that was financed by his employer. It should be clear, therefore, that this measure does not introduce a new factor into our revenue law but rather permits self-employed taxpayers and employed taxpayers not now covered by pension plans to defer taxes on certain portions of their current income. The setting aside of funds by the self-employed alone under this revised measure might possibly exclude a half-billion dollars annually from current taxation; on this sum, of course, taxes would eventually be payable.[2] The wide support given to the pension plans authorized under section 165 (a) by Congress since 1942 clearly establishes a favorable attitude toward the extension of similar privileges to those taxpayers not now covered. There would be no tax avoidance—only tax deferment. For this reason it would be better to extend our revenue legislation to cover them than to repeal section 165 (a), under which 16,000 pension plans have been approved.

The revisions and changes in this measure have occupied the attention of many persons. The special committee of the American Bar Association on Retirement Benefits for Lawyers has supervised the study and consideration during the past year that culminated in the hearing on May 13. The Bar Association committee was ably assisted by representatives of the American Medical Association, the American Dental Association, the American Institute of Accountants, the American Farm Bureau

---

Director, Bureau of Medical Economic Research, American Medical Association.

[1] Postponement of Income Tax on Income Set Aside for Retirement, Hearing Before the Committee on Ways and Means, House of Representatives, Eighty-Second Congress, Second Session, on H. R. 4371, H. R. 4373, H. R. 3456, H. R. 1173, H. R. 5847, and H. R. 7426, May 13, 1952, United States Government Printing Office, 1952.

[2] Footnote 1, page 47. According to the Treasury Department analysis of the original bill, the maximum conceivable revenue loss would be 3.7 billion dollars. Their statement is that "if 25% of the eligible individuals were to take full advantage of the bill, the current revenue loss would be nearly one billion dollars." If you change the 25% to 10%, which I consider a more reasonable estimate (one-third of the eligible persons excluding, on the average, one-third of the amount excludable = ⅓ × ⅓, or, roughly, 10%), the resulting current revenue loss would be 0.25 billion dollars. If we assume that 50% of my excludable amount of one-half billion dollars would be a loss in current revenue, then the difference between our two estimates is the difference between my 0.25 billion dollars and the 0.37 billion dollars. This is not a great difference, and I feel reasonably sure that their estimate could be lowered to mine, or even below mine, if they were basing it on the self-employed alone, or if they were basing it on the revised bill.

A half-billion dollars is 1.5% of the 36 billion dollar income of the self-employed in 1950. (The maximum excludable is 10%.) Since an unknown portion was a return on investment and, therefore, not earned income as defined in the Keogh-Reed bill, a considerable portion of that income would not be excludable under this bill. On this basis a half-billion dollars would obviously be a very high estimate. In 1950 the average income of the 10 million self-employed was $3,400 as compared with $3,200 for all 60 million gainfully employed. Personal savings for all persons in 1950 were $10.7 billion or 4.8% of total personal income. If the self-employed saved 4.8%, they would have saved not more than $1.8 billion. If they had put one-fourth to one-third of their personal savings into restricted retirement funds authorized by this bill, they would have excluded roughly a half-billion dollars, a high estimate when one considers the unattractiveness of the restricted retirement fund as an investment. Few eligible taxpayers under 40 to 50 years of age would consider it an attractive investment. Certainly most of the personal savings would still be invested in other forms, such as buildings, working capital, government bonds, and stocks.

Employers paid $1.56 billion as payroll taxes under the Social Security Act, as amended, in 1951. This was business expense that will never be taxable to either the employer or the employee. Probably taxes are being deferred on at least twice that sum on account of the payments made by employers to pension plans approved under section 165 (a). Thus, by several methods of estimate, the latter sum will be increased by less than one-sixth on account of exclusions by the self-employed under the Keogh-Reed bill. Further study will be required for an estimate of the amount that would be excluded by the pensionless employed who would be eligible under this bill because their employers do not have pension plans.

To me, the most significant point in the Treasury's analysis of the original Keogh-Reed bill is the last paragraph, which I interpret to mean that the Treasury admits that 10 million self-employed taxpayers are discriminated against by being excluded from section 165 (a) and that the Treasury would remedy this obvious discrimination by repealing section 165 (a), thereby jeopardizing the pension expectations of employees under more than 16,000 approved pension plans.

Federation, the Author's League of America, the American Federation of Radio Artists, the National Society of Professional Engineers, the Conference of Actuaries in Public Practice, the Association of Stock Exchange Firms, the Society of Industrial Designers, the American Institute of Chemists, the Investment Counsel Association of America, the United Bondholders of America, the American Veterinary Medical Association, the National Federation of Business and Professional Women's Clubs, and many state and local units of these great national organizations, many of whose members are self-employed because of the dictates of custom and law.

The list of changes made by the revised bills follows. No attempt has been made to arrange these changes in order of importance.

1. Several persons who testified on May 13 noted that the original bill provides only one method by which the excludable amounts could be invested, that is, through a trust fund established by ". . . a bona fide agricultural labor, business, industrial or professional association or similar organization for the exclusive benefit of its participating members. . . ." Accordingly, the new draft provides the eligible taxpayer with the option of purchasing a retirement annuity contract from an insurance company, provided the insurance contract contains the same restrictions as the restricted retirement fund. This additional method would avoid forcing any professional man to belong to a professional society as a condition for obtaining benefits under this measure and would, furthermore, give the large life insurance companies an equal opportunity to interest eligible taxpayers in using insurance company annuity contracts as a method of saving for old age. Moreover, the restrictions in this revised measure are so great that the combined efforts of banks, trust, and insurance companies may actually be insufficient to induce large numbers of eligible taxpayers to forego current consumption and save some of their earned income for old age. With more institutions employed in the development of this voluntary pension system, more persons now outside of pension plans will be encouraged—even urged—to set aside for old age some of their earnings during the working years of their lives. During the past 17 years Congress has repeatedly expressed approval of the general objective of inducing more persons to save for their old age. This voluntary pension system would require deliberate family budgeting of such savings.

2. No subject was discussed oftener during the hearing than the limits on the amount excludable annually, which the original bill has set at $7,500 or 10% of earned income, whichever is the lesser. The members of the committee were impressed with the general argument advanced during the hearing of May 13 that these limits were possibly too generous for the young and too severe for those who are now old. Consequently, the revised draft places an over-all lifetime limitation of $150,000 on the excludable amounts, that is, 20 times $7,500. Also, eligible taxpayers now over 55 years of age may exclude more than 10% of their earned income during the period 1953 to 1972.

Since the normal working period of life comprises about 40 years, a lifetime limit of $150,000 means that the maximum amount of $7,500 could be set aside annually every other year, or during half of the traditional 40 working years, by any eligible taxpayer fortunate enough to earn $75,000 in each of those years. For all practical purposes, this would cut the $7,500 in half and permit $3,750 to be excluded in each of the 40 working years, or the equivalent thereof, by this extremely fortunate person. While effectively cutting this annual limit in half, the revised bill still allows some flexibility; moreover, the amount of pension that the man earning $37,500 a year could finance by excluding $3,750 in each of 40 years will, under this new set of limits, be almost as much as the pension that could be financed by a man earning $75,000 a year who would make only 20 maximum payments during his lifetime. Thus, this new set of limits not only effectively reduces the annual limit but gives those who make less than $75,000 a year an advantage by permitting them to exclude 10% of their earned incomes in more years.

There has also been added under the Special Rule a provision for the exclusion of additional amounts by those who are now between 55 and 75 years of age. In many of the 16,000 pension plans approved under section 165 (a), the employer sets aside large sums of money to finance past-service credits for employees who had worked for him for a considerable length of time before the establishment of a pension plan. A practical counterpart for these past-service credits has been provided under the Special Rule, which would be in effect from 1953 to 1972 and would not apply to eligible taxpayers who will attain age 55 after Jan. 1, 1952. It provides that the amount annually excludable between the 55th and 75th birthdays shall be increased by an amount equal to 1% of the taxpayer's earned net income, or $750, whichever is the lesser, multiplied by the number of full years of his age in excess of 55 determined as of Jan. 1, 1952. But his multiple cannot exceed 20, nor can this additional amount be excluded after the taxable year in which the taxpayer attains age 75. Since the youngest eligible taxpayer is now 56 years of age and will attain age 75 in 19 years, it follows that this provision will expire in the calendar year of 1972. A number of tables presented at the hearing indicated that at the premium rates currently being charged by life insurance companies the maximum monthly cash refund annuity starting at age 75 (not at age 65) that could be financed under this Special Rule would be $1,206 a month—for a person now age 59 who would have an earned income of $75,000 in each of his next 17 years. It is hard to imagine such a fortunate person. Since the lifetime limit of $150,000 also applies to eligible persons over age 55 who would come under this Special Rule, the expected monthly pension starting at age 75 for this person now age 59 would be reduced from $1,206 to $1,013 a month.

Now let us turn from the question of limits on the amounts annually excludable from taxable income to the amount of the pension that could be financed. Tables were introduced during the testimony that revealed that very few younger taxpayers under the General Rule could, at present annuity rates, expect to finance a pension of much more than $1,000 a month starting at age 70. As stated before, under the Special Rule almost no one now over age 55 could finance a monthly pension starting at age 75 in excess of $1,000 a month on a cash refund basis. Thus, the revised limitations will prevent any eligible taxpayer from financing a pension of much more than $1,000 a month starting at age 70 or age 75. Testimony was also given indicating that approximately two-thirds of the pension plans approved in recent years under section 165 (a) permitted maximum pensions of more than $1,000 a month—usually starting at age 65, not at age 70 or 75, when the cost is less—and the remaining one-third of the recently approved plans established a maximum of less than $1,000 a month starting at age 65. It was concluded that the monthly pension target of $1,000 a month provided in this revised draft is a very reasonable counterpart of section 165 (a) for the self-employed and those employed not now covered by pension plans.

Simple arithmetic indicates that a pension of $1,000 a month and $12,000 a year is equal to 16% of the $75,000 of earned income a year that would be the minimum amount that a person would have to earn if he made the maximum contribution of $7,500. Do most industrial pension systems allow a maximum pension of more or less than 16% of average earnings? Only 3% of the new pension plans aim as low as a pension of less than 20% of average earnings. The man earning $37,500 could get a pension equal to 32% of his average earnings, and this 32% would be about the highest percentage that anyone could attain under this bill. Hence, by the test of the percentage relationship between the monthly pension and average earnings, this bill is far more restrictive than section 165 (a) in actual practice.

The bill cannot be considered a "rich man's" bill in any sense of that term. If any better set of limitations had been developed, the authors of the bill would not have proposed a lifetime limitation of $150,000 on the amounts excludable from taxable income. The averaging formulas developed under the regulations promulgated under section 165 (a) have prevented discrimination against low-paid employees. But formulas cannot be applied to an individual. The lifetime limitation is merely the best suggested method of providing the counterpart of section 165 (a). There was no necessity for such a limitation in the language of that section, because it applied to groups. Only by examining the limitations in pension plans approved thereunder can the reasonableness of this lifetime limitation be demonstrated.

3. So much for the maximum pension which is highly theoretical because so few persons could earn $75,000 every year for most of their working lifetimes. We now turn to the average pension. Unrefuted testimony supported by elaborate tables was given on May 13 that estimated the average pension a physician, a lawyer, and a dentist could receive under this revised bill on the basis of the Department of Commerce surveys of the incomes of lawyers in 1947, of dentists in 1948, and of physicians in 1949. The average monthly pension on a cash refund basis starting at age 70 for all members of the profession now under 70 years of age would be $208 for physicians, $106 for lawyers, and $140 for dentists. Furthermore, it was estimated that under the Special Rule for those now over age 55 the average monthly pension at age 75—not age 70—would be $131 for physicians, $121 for lawyers, and $72 for dentists. These average amounts of pension for the members of these three professions will give the members of Congress a much clearer idea of the monthly amount of the typical pension under this revised draft than will any consideration of the maximum theoretical pension. Unfortunately, the Committee on Ways and Means was not given any data on May 13 on average expected pensions for the members of other professions and other groups of eligible taxpayers. This was attributed to the unavailability of income surveys of the other professions. The plain fact is that pensions cost a lot of money, and the members of the Committee were more impressed with the estimated average pensions given at the hearing than with the theoretical maximum pensions in weighing the arguments for and against this proposed voluntary pension system. The amounts excludable annually from taxable income when read separately may still seem large to some persons even with the lifetime limitation of $150,000, but anyone who will examine the probable average amount of pensions under this revised draft will not consider the limits too high. Indeed, as time passes it is probable that the limits may need to be raised in order to encourage this group of more than 10 million gainfully employed citizens to provide adequately for their old age out of their own earnings. They have no employer to pay it for them. This bill would encourage citizens to save some of their own money for old age and to pay taxes on those pensions during their old age.

4. So much for maximum pensions and average pensions expected under this revised draft. The vital question regarding this voluntary pension system is neither of these. The vital question is how much of the maximum pension and how much of the average pension would be attributable to the advantage of tax deferment. Each taxpayer is going to pay for these pensions out of his own pocket. No employer, no unit of government is going to pay him one cent for pensions. No one will be credited with additional amounts in his retirement fund when other employees quit or die. The only gift to the taxpayer, the only way in which this bill would encourage the self-employed and those not covered by pension plans to save earnings for old age during their working periods of life is the enticement of paying lower taxes during the retired years on the pensions as they are received than they would have paid on the premiums (excludable amounts) during their working years, that is, the prospect of reducing total lifetime taxes. On the average, no more than one-fifth, or possibly one-fourth, of these pensions could be considered the real benefit being conferred upon the taxpayer by reason of tax deferment. If this estimate may be accepted for the present, the question before Congress is whether such a benefit of one-fifth or one-fourth of these pensions is sufficient to give these citizens who are excluded from section 165 (a) the counterpart of tax deferment benefits that employees are currently obtaining under that section. It must be stressed that the amount of the pension is four or five times the amount of the benefit that this revised bill would confer upon these taxpayers. After 12 months of study there is still reasonable doubt that the true benefits under this revised bill are actually sufficient to provide equality for those outside the scope of section 165 (a).

The term "expected benefits" is used, for no one can predict the level of income tax rates in future years such as 1973 or 1981. Every taxpayer who would exclude sums under this revised bill is gambling with the future of our income tax rates. Presumably, he would pay smaller taxes during his retired years than during his working years. This statement is reasonable if we are thinking about two men in 1952, one of whom is 45 and now at or near the peak of his earning period of life, and the other 75 and probably retired. We must think about future calendar years, for this bill is concerned with persons as they pass through time, and the actual savings in taxes offered by this bill are highly problematical. Income tax rates have moved upward during the last two decades. It is certainly true that if we turn back the pages 15 or 20 years we could find examples of persons who, if this bill had been available to them 15 or 20 years ago and they had set aside sums of money during their working years in the expectation of paying lower taxes during their retired years starting in 1952, would have found that instead of having a tax savings they would have had a tax loss. Who knows the future of income tax rates?

The option of taking the benefits in a lump sum and paying in turn a capital gains tax is provided in section 165 (a). Therefore, it has been provided in this bill. The grave uncertainties about the future level of income tax rates warrant this capital gains option. For that matter, the future level of the capital gains tax rate is also uncertain.

5. In the original bill any taxpayer covered by a pension plan was permitted to exclude under the bill the difference between the limits of (10% and $7,500 described above) and the amount his employer was currently paying into a pension fund approved under section 165 (a). Testimony given at the hearing indicated that such a provision would be extremely difficult to administer. In the first instance, many employers do not actually know how much they are contributing annually to the credit of their younger employees, especially before the time when the employer's contributions are vested in the employee. Many approved pension plans provide that, if the employee does not continue in the service of the employer until retirement, any contributions made by the employer to the credit of the severing employee shall be distributed by formula to the credit of the continuing employees. Thus it would be very difficult for such an employer to determine—even if required to report annually on something like a W-2 form—the current contribution to the pension fund for a named taxpayer. Furthermore, many taxpayers not employed by taxable employers, such as civil servants, firemen, policemen, school teachers and employees of charitable, religious, and scientific organizations, are covered by pension plans that do not need to be approved under section 165 (a). In the interest of simplicity it seems wise to exclude from this revised draft all persons who are covered by any kind of a pension plan, especially the younger employees, who can expect to be covered after completing a specified number of years of service and those who have actually retired and are now receiving pension payments under such plans. It is true that their exclusion will not produce equity in every case, but excluding them seems imperative. There was even some discussion at the hearing of excluding all employed persons and restricting the provisions of this bill to the 10 million self-employed. The authors of the bill did not go that far, because they realized that there are many employed persons, especially those who are employed for short periods of time, who are not now and who probably never will be covered by employer-employee pension plans. Hence the coverage of this revised bill is a compromise between the extremes of covering every taxpayer and covering only the self-employed.

6. There are thousands, perhaps millions of taxpayers who have extreme fluctuations in income. Some of these and other taxpayers might find it impossible to set aside reasonable amounts necessary to finance retirements unless some carry-over provision were developed. Hence an entirely new section was introduced, section (4), which provides for a carry-over of unused exclusions for a period of not more than five years. No additional exclusions from taxable income made under the Special Rule in the revised bill by those now over 55 years of age can be made under the carry-over provision; that is, the carry-over provision applies only to contributions made under the General Rule, most of which will be made by younger persons. The hardship that this carry-over provision is designed to alleviate is found extensively in the entertainment field and among self-employed

persons engaged in architecture and engineering. This is not to say that there are no other groups that have described their need for this type of provision, which, as noted above, has been carefully limited to a five year period and must function within the limit of $7,500 per year.

7. Last, we shall consider the severe restriction on the distribution of the proceeds of the restricted retirement fund and exactly similar restrictions on the restricted retirement annuity. In simple language, these provisions would prohibit any withdrawal from these savings funds until the taxpayer reached age 65. In the original bill the age was 60; several members of the Committee on Ways and Means indicated a preference for age 65, the retirement age specified in the Social Security Act. This restriction will greatly deter the use of the provisions of this bill and will certainly confine its use to those who sincerely and honestly want to save for old age and for no other reason. Consider a lawyer aged 40 and his wife contemplating setting aside 10% of his earned income under this measure. First, they would have to decide that they did not want to spend the money, as there would be no regular deduction from their monthly pay check by the accounting department of a corporation. Thus the decision to save would have to be made deliberately. Second, they would realize that they could not touch this fund for any of the financial crises that the family might encounter before the husband reached age 65, 25 years hence. Would that seem to you to provide a serious temptation to abuse the privileges provided by this bill? If you will think back over your own lives, you might conclude that you would have preferred paying the income tax currently and then investing the remainder in some fund that you could tap for the ordinary financial crises that your family might encounter, for the ordinary rainy days for which persons have always saved.

Because of the unattractiveness of this investment opportunity, it was provided that, in the event of permanent and total disability continuing for a period of more than three months, the taxpayer would be permitted to make withdrawals from his savings. There are many financial crises in the family other than the disability of the breadwinner, but withdrawals cannot be made in order to meet any of these other types of crises. Time and experience may demonstrate that this restriction is so severe that it will have to be modified to encourage eligible taxpayers to save for old age. It is one of the most important reasons back of the contention that the use of the provisions under this bill will be so limited that the Treasury will have little reason to worry about the loss of current revenue.

There is, of course, the possibility of repealing section 165 (a) in order to provide equity between the persons not covered by the pension plans and those who are covered by pension plans; or, in other words, between those who now enjoy tax deferment privileges in the financing of their pensions and those who do not. But the repeal of section 165 (a) does not seem to merit any serious consideration. The repeal of that section would destroy most of the 16,000 pension plans and darken the future of millions of loyal employees who are confidently expecting pensions under their company pension plans. Such a solution seems cruel. Rather the solution is to provide for the self-employed and those not covered by any kind of pension plan the privileges of tax deferment that persons covered by pension plans enjoy and expect to continue to enjoy.

Our problem is to rectify the error of 1942, the error Congress made in excluding the self-employed from the tax deferment pension benefits of section 165 (a). We have given a cold shoulder to 10,000,000 self-employed persons. Our problem is also to provide reasonable pension opportunities for employed persons not actually covered by pension plans 10 years later. Until we close this gap we shall have failed to complete the new social theory enunciated in 1935 and implemented in 1942. The heart of this new social theory is that pensions are good and that the Federal government should encourage them. All would agree that pensions are good. But many would not want the federal government to encourage pensions. It seems to me, however, that none can disagree that, if the federal government does encourage pensions, it should encourage pensions for all and not merely for those who are employed by employers who have established pension plans.

COUNCIL ON MEDICAL SERVICE

This is the second in a series of studies made by the Committee on Indigent Care of the Council on Medical Service concerning local plans for medical care of the indigent. A general introduction to the series and the first of the Committee's studies (Erie County, New York) appeared in the May 10, 1952, issue of The Journal, *pages 188-191.*

MEDICAL CARE FOR THE INDIGENT IN MADISON, WISCONSIN

This report is a study of medical care available for indigent and medically indigent residents of the city of Madison in Dane County, Wisconsin. Dane County has a population of approximately 165,000 and is primarily a farming and dairying county, with some small industries. Including the 14,000 students at the University of Wisconsin, 100,000 persons, 61% of the county's population, reside in Madison, the state capitol and county seat and the main business center of the county.

Public assistance is provided on a county-wide basis, but each of Dane County's 60 political subdivisions is responsible for general assistance to its own indigent residents. For this reason, a study of welfare medical care in Madison is considered more practical than a survey of the entire county's programs.

Table 1.—*Estimated Average Monthly Coverage, Dane County and Madison, 1951*

	Dane County	Madison
General Assistance (including medically indigent)	377*	230
Public Assistance	3,651	2,227*
Old Age Assistance	2,175	1,327*
Aid to the Blind	66	40*
Aid to Dependent Children	1,350 (600 cases)	823*
Aid to Permanently and Totally Disabled	60	37*

* Estimate, based on percentage of county's population resident in Madison.

ELIGIBLE POPULATION

Residents of Madison are eligible for general assistance medical care when admitted to the welfare department's relief rolls or deemed medically indigent by the department. An average of 230 residents received such aid monthly in 1951.

An estimated 3,651 persons in Dane County received aid monthly from public assistance programs in 1951. In table 1 are given figures on the various types of assistance, with the proportion of the population aided by each program assumed as the same in city and county.

According to the estimate in table 1, approximately 2,457 Madison residents per month, about 2.5% of the city's population, received general or public assistance and were therefore eligible for medical care at public expense in 1951.

ADMINISTRATION

The general assistance program is administered in Madison by the city welfare department, which determines eligibility of both indigent and medically indigent clients. Each client's eligibility is certified monthly. The welfare department is also in charge of planning and authorization of benefits, subject to the approval of the city council, to which the department makes monthly and annual reports. Any appeals by clients are made to Madison's director of welfare.

The public assistance program for all of Dane County is supervised by the Dane County pension department. Eligibility for aid to the blind and aid to the permanently and totally disabled is determined by the state department of public welfare. The county agency determines eligibility for old age assistance and aid to dependent children and is responsible for the planning, authorization, and approval of bills for all public assistance programs. Certification of clients lasts at least a year before a recheck is necessary. The county pension department reports to the county board of supervisors and to the state department of public welfare. Clients may appeal county decisions to the state authorities, who must, by law, provide a "fair hearing." Both programs provide for control of abuses by patients; for example, a patient who changes physicians too frequently can be required to choose a single physician to treat him for the duration of his illness.

Complaints against physicians are referred to the Dane County Medical Society. The society's medical coordinator reviews complaints concerning fees or refusal to accept welfare cases and can, if necessary, refer the complaint to the society's board of censors for further consideration as to disciplinary action.

SERVICES AVAILABLE

Benefits provided by the general and public assistance programs are sufficiently alike to be discussed jointly in this report. All health services are potentially available to anyone on any of the programs and are generally provided on a "free choice" basis. Each person is treated according to his needs, and the extent and course of treatment is usually decided on by the client's physician. Home and office calls are provided by physicians on a free choice basis. Specialists' care, in or out of the hospital, is provided on referral by the attending physician. The patient may be referred to a specialist or to a group clinic of his choice.

Madison does not have a city or county hospital; as a result, hospitalization, when recommended by a physician, is available on a free choice basis. The patient may be admitted to the hospital without prior authorization from welfare agencies, and has free choice of a physician for in-hospital care. Provisions for a physician's first visit and for hospitalization without prior authorization insure that there will be no time lapse between the request and receipt of most services.

Madison has no public clinics or hospital outpatient clinics except some specialized clinics maintained by the health department. There are approximately 15 private group practice units located in various parts of the city to which welfare clients may go if they wish to do so. Welfare patients are treated by physicians in the same way as private patients. Any recommendations for services or appliances made by the attending physician are authorized. Drugs, as prescribed by the attending physician, are provided by private pharmacies and paid for by the authorizing agency. Home nursing and invalid home care are also available when necessary or advisable.

A person who needs funds because of illness and who is not eligible for either general or public assistance may receive help from the Community Chest agency in Madison. This agency will help pay for both medical care and hospitalization. Patients are usually referred to the Chest agency by the hospitals, so that a double check is obtained as to eligibility and need.

PROVIDERS OF SERVICES

The patient may be treated by any one of the approximately 300 physicians in Madison, except the nonpracticing staff members of the University of Wisconsin Medical School. The physician need not be a member of the Dane County Medical Society to treat welfare patients, and no participation agreement is required. The client has free choice of physician, even during hospitalization, and has free choice of specialist if specialized treatment is advised by the attending physician. Fifteen group practice units in Madison also participate in the program.

Madison's health department operates well-baby, immunization, and chest clinics, which are open to anyone, whether or not referred by a physician. The health department clinics perform no therapy; the chest clinic is diagnostic and performs fluoroscopic examinations. The health department also employs a full-time health educator whose services are available to any agency interested.

All hospitals in Dane County may accept welfare clients. The general hospitals in Madison and the number of beds in each are given in the following tabulation.

Madison General Hospital	177
Methodist Hospital	132
St. Mary's Hospital	230
Wisconsin General Hospital	750

Wisconsin General Hospital is primarily a teaching institution, maintained by the state; however, it will accept welfare patients from any county in Wisconsin. Each county is allotted a quota for the care of public patients at the state hospital, and the cost of care for these patients is shared by the state and the county. When the quota is exhausted, the county assumes full financial responsibility for any additional public patients admitted to the hospital. There are two nursing homes in Madison itself and approximately 11 in the rest of the county. Home nursing is provided on a contract basis by the Visiting Nurse Service in Madison.

PAYMENT FOR SERVICES

Payments to private physicians are made according to a fee schedule developed by the Dane County Medical Society and the city welfare department and accepted by the county pension department for the whole county. Fees are approximately 80% of conservative normal fees and cover all phases of surgery and medicine, including in-hospital physician services.

The fee for home calls is $3.00 during the day and $4.00 after 7 p. m., with a $2.00 fee for each additional patient seen during the visit. Office calls are $2.00 each. The physician is paid for visits to a hospitalized patient at a rate of $2.00 per visit for the first 10 days, $1.00 per visit for the next 20 days, and $1.00 per visit for the first 10 days of each succeeding month. Physicians who treat general assistance patients submit their bills to the city welfare department. The department sends the money for payment to the medical society, which pays the physician according to the fee schedule, less 5% for administrative costs.

Physicians providing care under the aid to dependent children program are paid directly by the county pension department. Old age assistance and aid to the blind clients who require medical care receive an increase in their monthly aid checks and are expected to pay the physician out of this amount; however, when the grant is used up, the pension department pays any further medical costs directly to the physician. There is no supplementary medical budget for aid to the permanently and totally disabled. Clients of this program receive their medical services as general assistance patients, and the service is paid for by the city welfare department.

Pharmacies are paid directly for prescriptions filled for all classifications of welfare clients and hospitals are paid by the welfare agencies according to fixed *per diem* rates.

COSTS AND FINANCIAL SUPPORT

The general assistance program is supported by city tax funds. The state and county governments share the medical costs of public assistance; the state provides 35% of these funds, and the county provides the rest. Indigent persons who have lived in Wisconsin less than one year and need medical assistance receive care at the expense of the state department of public welfare.

All appropriations are made annually. Budgets for general assistance must be approved by the city council and those for public assistance by the county board of supervisors. Supplementary budgets may be submitted if the funds allocated are insufficient. The agencies are required by law to supply adequate funds; the city must bond itself, if necessary, rather than curtail its program.

The cost figures given in table 2 are for the first six months of 1951. Official figures for public assistance expenditures are available for Dane County only; however, Madison has 61% of the county's population, and, for the purposes of this study, city expenditures have been assumed to be approximately in proportion to population. As previously noted, medical care for the permanently and totally disabled is provided from general assistance funds.

TABLE 2.—*Costs of Welfare Programs*

	Dane County	Madison
General Assistance	....	$ 22,773.45
Public Assistance	$199,896.82	121,937.06 *
Old Age Assistance	149,250.29	91,012.68 *
Aid to the Blind	2,619.25	1,597.74 *
Aid to Dependent Children	48,027.28	29,296.64 *

* Estimate, based on percentage of county's population resident in Madison.

With the estimated figures as a basis, the total amount expended on welfare medical care in Madison during these six months would be approximately $144,710.51, or almost $300,000.00 a year.

Following are estimates of the average monthly cost of medical care in Madison for each of the four programs and for each eligible client, as well as the monthly cost of some of the major items provided. For the purposes of this tabulation, the 37 clients estimated as eligible for aid to the permanently and totally disabled have been included with those eligible for general assistance.

	G. A.	O. A. A.	A. B.	A. D. C.
Estimated monthly cost.......	$3,795,58	$15,173.78	$266.29	$4,882.77
(Estimated number eligible)..	(267)	(1,327)	(40)	(823)
Cost per eligible person.......	14.22	11.44	6.61	5.93
Physician's care	4.08	2.60	1.38	2.45
Drugs	1.71	1.12	1.53	0.81
Hospitalization	5.37	2.77	0.20	0.91
Nursing home care........	2.49	4.34	2.64	....

The average cost of medical care per eligible client for Madison's entire welfare program during this period, based on the above figures, was about $9.82 per month.

MEDICAL SOCIETY RELATIONSHIP

The medical coordinator of the Dane County Medical Society occupies a key position in the city and county medical aid program. His duties are "to make certain that the patients, the doctors and the various agencies are mutually satisfied with the services and the allowances" agreed to by the medical society and the welfare agencies. The coordinator, who serves without pay, acts on behalf of the medical society in controlling abuses by physicians, reviewing complaints, and helping to settle disputed fees. He serves as liaison officer between the medical profession and the welfare agencies and, if necessary, may refer cases directly to the society's board of censors. Much of the success of the total program is due to the work of this office.

It is largely through the efforts of the Dane County Medical Society and its coordinator that the patient is assured of completely free choice of a physician not only for home and office but also for hospital care. The fee schedules established by the society and the welfare agencies provide for fair reimbursement for all services provided by the physician, with compensation according to the treatment given.

It is noteworthy that treatment can be provided by any physician in the county and that no participation agreement is required. Thus, the choice of physician is completely free, not even limited to society members, although the society has a major part in the program through the fee schedule and the coordinator and is used by the city welfare department to distribute payments to the individual physicians.

SUMMARY

The medical aid program for recipients of general assistance and public assistance in Madison achieves reasonably complete unity and coordination through the office of the medical coordinator of the Dane County Medical Society. The services offered under the two programs are almost identical, and payments to physicians are in accordance with a fee schedule agreed on by the welfare agencies and the medical profession. The clients of any relief program are eligible for home and office care, hospitalization, home nursing, convalescent care, and prescribed drugs. As a result, relief clients have potentially available to them every medical service provided in the county, and, because the services are the same for all relief groups, there is little incentive to "jump" from one program to another in order to obtain more and different types of medical service.

For those who are unable to meet the qualifications of general or public assistance but who need aid to pay for medical care, the Madison Community Chest agency has a program of financial assistance. Thus, any person in Madison who finds it impossible to provide himself or his family with medical care has some program of assistance to which he may turn.

A number of features of the Madison program are especially noteworthy. A completely free choice of physician, with the same physician caring for the patient over a period of time and when hospitalized, is the best assurance of a good quality of medical care to the indigent. The fact that authorization is not required before a patient calls a physician means that there will be no gap between the request for and receipt of services. In addition, physicians are paid for all services, thus placing the indigent on a par with private patients and eliminating any stigma that might be attached to indigency.

The role of the medical society of Dane County is admirable. It not only negotiates agreements between official agencies and physicians and sees to it that the physicians give service to all indigents under the terms agreed on but it polices its own membership. The only weakness here is that the control of abuses by physicians is vested primarily in one man. At the present time this man handles the position extremely well. His honesty and fortitude of character are especially suited for this responsibility. It would seem, however, that since the medical coordinator's job is such an all-important cog in the machinery his authority should be shared by a committee of no less than three, so that, in the event one person is unable to carry on, the program can be assured of continued strength and continuity of policy.

From the client's standpoint the program is certainly successful in providing complete medical care with a minimum of delay and red tape. The main objective of the program is to render adequate medical care to relief clients, and in this there can be little doubt that Madison has succeeded.

BUREAU OF LEGAL MEDICINE AND LEGISLATION

MEDICOLEGAL ABSTRACTS

Devices: Chiropractor Not "Physician" Under Federal Food and Drug Act.—This was a proceeding by the United States for the condemnation of 22 devices known as Halox Therapeutic Generators. The case was heard in the United States district court, southern district, California.

A Halox Therapeutic Generator is a device for the electrolysis of a sodium chloride solution. It is housed in a leatherette-covered plywood cabinet, its base being approximately 12 in. by 15 in. and its height approximately 12 in. At the front of the cabinet is a control panel. Inside the cabinet there is a glass jar partly filled with a saturated sodium chloride solution into which carbon electrodes extend, and when the generator is in operation electricity is carried to these electrodes. As a result of the electrolysis of the salt solution, chlorine gas is produced. A small electric fan blows a current of air through the jar and out through a rubber hose. Thus a mixture of air and chlorine gas goes into the tube. This mixture is then administered to patients receiving the "chlorine inhalation therapy" by having the patient hold the rubber tube to his nose and inhale.

Administrative regulations issued pursuant to the Federal Food, Drug, and Cosmetic Act exempt from the labeling requirements devices that are delivered to physicians for use in their professional practice, provided information adequate for the use of such a device by the physicians is readily available. All, save 1, of the 22 devices involved in this suit were shipped to W. G. Keys, who held a valid license as a chiropractic physician from the state of California. Keys maintained several offices in Los Angeles County at which these devices were used by him in his practice. The remaining generator was in the possession of another chiropractor, C. J. Henaghan. At the outset, said the court, it is clear that the generators did not bear adequate directions for use. In fact, they bore no directions for use. This was admitted by the claimant who argued that the devices were exempt from such requirement by virtue of having been shipped or delivered to physicians to be dispensed by physicians in their professional practice. It is at once apparent, continued the court, that the claimant can succeed only if a chiropractor is a "physician" within the meaning of the regulations. The regulations define "physician" as "only those physicians, dentists and veterinarians who are licensed by law to administer or apply such drug or device." Thus the persons to whom the devices were shipped must, first of all, be physicians. Only if they are physicians is it necessary to inquire into the matter of their authority to administer or apply the device.

In its broadest sense, said the court, the term "physician" includes anyone exerting a remedial or salutary influence, as a physician of the soul; however, the court did not believe that the term as used in the regulation was intended in the broad sense. In Webster's New International Dictionary, 2nd ed., 1949, one definition of "physician" is: "A person skilled in physic or the art of healing." In the same volume "chiropractic" is defined as "a system for the practice of adjusting the joints, especially of the spine, by hand, for the curing of disease." Thus a chiropractor is one skilled in the art of healing, in a limited manner, although not one skilled in physic, since this latter term refers to the practice of medicine. In Webster's dictionary a second definition of "physician" is: "one duly authorized to treat diseases, especially by medicines; a doctor of medicine; often distinguished from a surgeon." The chiropractic law of California provides in part: ". . . any licensee under this act who uses . . . the term 'physician' . . . or any other letters, prefixes or suffixes, the use of which would indicate that he or she was practicing a profession for which he held no license from the State of California, . . . shall be guilty of a misdemeanor. . . ." It follows, said the court, that one who is licensed to practice chiropractic in the state of California is not a physician by virtue of such license. The record is devoid of any evidence attributing qualifications as physicians to the chiropractors concerned here.

There is, in addition, a more compelling reason for holding that the seized generators were not exempt from the requirement that they bear adequate directions for use. The exemption regulations define a physician as a physician who is "licensed by law to administer or apply" the drug or device in question. Thus, even if the term "physician" is broad enough to include chiropractors, it includes only those chiropractors who are licensed by law to administer or apply the drug or device. The authority of a licensed chiropractor is defined by law which provides: "One form of certificate shall be issued by the board of chiropractic examiners, which said certificate shall be designated 'License to practice chiropractic,' which license shall authorize the holder thereof to practice chiropractic in the State of California as taught in chiropractic schools or colleges; and also, to use all necessary mechanical, and hygienic and sanitary measures incident to the care of the body, but shall not authorize the practice of medicine, surgery, osteopathy, dentistry or optometry, nor the use of any drug or medicine now or hereafter included in materia medica." The scope of this authority, said the trial court, has not been defined by the supreme court of California, but appellate courts of California have had occasion to consider the question. On the basis of their decisions it is clear that a chiropractor licensed by the state of California is not authorized to treat diseases and ailments by mechanical means. As we have seen, the parties are agreed that the generators under seizure were intended for use in the conditions of arthritis, sinusitis, hay fever, and bronchitis. All these conditions are diseases and as such could not be treated by chiropractors by means of the Halox Therapeutic Generator. It follows that the seized generators were not exempted by the regulations, since they were not shipped to physicians who were licensed by law to administer them.

There is yet a third reason, said the trial court, why the seized devices were not exempted by the administrative regulations. Those regulations require that information adequate for the use of such device by physicians be readily available. By affidavit, Dr. Thienes, M.D., chairman of the department of pharmacology at the University of Southern California Medical School, stated that the use of chlorine gas in an effective antiseptic concentration would be too irritating to be withstood by the average person and that concentrations less than this are ineffective for any purpose. He stated that chlorine gas to be safely inhaled for even a short time requires a concentration of less than 10 ppm. The results of tests made by a chemist employed by the Food and Drug Administration indicated that a constant output of such a safe amount was obtained at only two dial settings. Yet nowhere is it shown that directions were available suggesting such dial settings. Furthermore, even at these settings the chlorine output varied throughout a three hour test period. Thus it is clear, the court concluded, that adequate directions were not available for the use of the generators.

Accordingly, the court held that the 22 Halox Therapeutic Generators must be condemned and disposed of by destruction in accordance with the provisions of the Federal Food, Drug, and Cosmetic Act. *United States v. 22 Devices, More or Less, Halox Therapeutic Generator, 98 F. Supp. 914 (1951).*

MEDICAL MOTION PICTURES

The Use of the Microscope: 16 mm., color, sound, showing time 19 minutes. Prepared by Dr. Merrill J. Shepro, University of Illinois. Produced in 1949 by and procurable on rental ($15) or purchase ($175) from Scientific Film Co., 6804 Windsor Ave., Berwyn, Ill.

This is a textbook type film designed for teaching students the correct and efficient manipulation and care of the microscope. It is composed of the following 12 text units: basic parts of the microscope; optical principles; types of microscopes; light source adjustment; adjustment of optics; slide preparation; correct sitting posture; technique of microscopy; oil immersion technique; cleaning of lenses; care of the microscope; and common mistakes of beginners.

In an effort to produce a textbook type of film in 20 minutes time, certain important phases have been omitted, some are incomplete, and others have been unduly emphasized. Since a great deal of the subject matter does not lend itself to the motion picture medium, most of the information presented is contained in the narration. It would therefore be impossible to digest all the material in one showing.

The following demonstrations are well done: method of determining the source of dirt; operation of field and aperture diaphragms; adjustment of the condenser; and adjustment of the intensity and the illuminated area.

In addition to the general criticisms, the specific point of indicating that a beginner should remove the objective while cleaning it can also be criticized. There is also a lack of clear labeling of parts. The photography is good; but the narration is constant and rapid, and the narrator's voice tends to be somewhat monotonous. The film may be of use in stimulating interest in the use of the microscope for the beginner or as a review for the advanced student.

Transplantation of the Vertical Recti for Lateral Rectus Paralysis: 16 mm., color, silent, showing time 14 minutes. Prepared by Conrad Berens, M.D., and Louis J. Girard, M.D., the Ophthalmological Foundation, New York. Produced in 1951 by the Photography Department of the New York Eye and Ear Infirmary. Procurable on loan or purchase from the Ophthalmological Foundation, Inc., 314 E. 14th St., New York 3.

An operation to provide lateral movement of the eye in the field of operation of a paralyzed lateral rectus muscle is described, and diagnosis of the condition is made by examination and history. The operation consists of recession of the medial rectus about 5 mm., resection of 7 mm. of the lateral rectus, and splitting of the superior and inferior recti tendons from their insertion into the sclera backward 5 to 7 mm. The lateral half of the superior and inferior recti muscles is attached, together with the resected lateral rectus, at the site of the former lateral rectus insertion.

The operation is done in such a manner as to preserve the integrity of Tenon's capsule. The tendons are reattached to the sclera with absorbable sutures, and the conjunctiva is closed with running silk suture. An illustrative patient is a young girl who shows lack of rotation of the left eye in the field of action of the left lateral rectus muscle before operation. Following operation, movement of the eye in this field is adequate and, apparently, conjugate with the right eye.

The film is designed to show operative technique and also to demonstrate the changes in action of the lateral half of the superior and the inferior recti from adduction to abduction. The photography is very well done. The film would be useful in teaching students of ophthalmic surgery and is recommended for residents and ophthalmological societies.

Abrasion with Sandpaper in Treatment of Accidental Tattooing.—A truck driver requested treatment for a bluish tattooing of his face, which had been caused about seven months before by an explosion of the gas tank of his truck. There were streaks and discrete bluish pigmented spots and patches on the left side of the face, especially the forehead and the infraorbital region. His co-workers frequently teased him for having a black-and-blue eye. An area about 2.5 cm. in diameter on the left cheek was anesthetized with procaine hydrochloride, and the skin over the area was treated by abrasion with sandpaper, no. 000, until bleeding was profuse. Within 48 hours a crust formed, which fell off in about five days, leaving a smooth pink surface. In about 10 to 14 days the area healed. Similarly involved areas were treated at weekly or biweekly intervals. Two months after the last treatment, examination showed excellent results and no cicatrization.

Early Diagnosis of Cancer of Pancreas.—The clinical records of 100 cases of cancer of the pancreas in which necropsy was performed showed that in 55 cases the symptoms or the findings were suggestive of cancer of the pancreas, while in 41 no evidence of pancreatic disease was revealed by the history, physical examination, or laboratory tests at the time of admission to the hospital. In 73 cases necropsy showed that cure was impossible at the time the patient was examined, either because metastases had developed or because the disease had extended locally to such an extent as to be inoperable. The diagnosis of cancer of the pancreas must be made early if surgical intervention is to offer any hope of cure. If pain in any part of the abdomen, either paroxysmal or constant, has developed recently, there has been an unaccountable loss of weight, and the results of physical examination and gastrointestinal roentgen ray studies are negative, a probable diagnosis of cancer of the pancreas is justified. In early cases of cancer of the body and tail there is no diminution of the pancreatic juice, and hence, if the patient is to be saved, the radical operation must be undertaken when only the symptoms mentioned are present. Bulkiness of the stools indicates absence from the intestine of pancreatic juice, as in no other condition are the stools so massive. Visible fat resembling butter or cream on the surface of the stools or in the surrounding fluid is pathognomonic of pancreatic disease. In order to demonstrate this evidence of pancreatic insufficiency the diet should contain a considerable amount of fat. When limited amounts of fat are fed, there is usually no visible fat on the surface of the stool. The presence of fat, fatty acids or soaps gives the feces a clay color, which is not caused by the absence of bile, as is usually thought. The significant finding on microscopic examination is the presence of large numbers of undigested muscle fibers, which may be studied by feeding the patient daily 100 to 150 gm. of finely chopped beef or ham given raw or lightly broiled. The secretin test will demonstrate deficiency of pancreatic juice. Serum lipase and serum diastase tests, although usually negative in cancer of the pancreas, should be employed whenever possible because, if positive, they are diagnostic of pancreatic disease. Contrary to the commonly accepted view, fever and pronounced leukocytosis are often present in advanced cases of cancer of the pancreas. Liver function tests and the demonstration of occult blood in the stools are misleading and needlessly delay operation.

Periodicals on file in the Library of the American Medical Association may be borrowed by members of the Association or its student organization and by individual subscribers, provided they reside in continental United States or Canada. Requests for periodicals should be addressed "Library, American Medical Association." Periodical files cover only the last 11 years, and no photoduplication services are available. No charge is made to members, but the fee for other borrowers is 15 cents in stamps for each item. Only three periodicals may be borrowed at one time, and they must not be kept longer than five days. Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted.

Streptomycin Therapy in Pulmonary Tuberculosis.—Of 85 patients with pulmonary tuberculosis, 42 were treated with streptomycin and 43 served as controls. Each patient in the streptomycin group received 0.1 gm. of the drug per 11 lb. (5 kg.) of body weight daily, with a maximum dose of 1.5 gm. The total daily dose was divided equally and given at eight hour intervals for 91 consecutive days. Follow-up observations were made at 3 month intervals for 12 months. The treated group showed greater improvement with respect to increase in body weight, decrease of fever, and decrease in sputum weight. Roentgenograms revealed definite improvement in the streptomycin-treated group. The proportion of sputum conversions was definitely greater in the streptomycin-treated group. The greatest improvement occurred immediately after three months of streptomycin therapy. Resistance appeared in approximately one-half of the treated patients after three months of streptomycin therapy. At the end of one year all available cultures in the treated group showed drug resistance.

Small Benign Gastric Ulcer.—Of 100 patients with small benign gastric ulcers measuring no more than 1 cm. in diameter, 20 also had a duodenal ulcer and 1 had peptic ulceration in four locations, including the upper gastrointestinal tract. Five patients had two or three gastric ulcers. Achlorhydria was observed in 10 patients, no free acid being demonstrated on at least two occasions following histamine stimulation plus a 12 hour nocturnal continuous drainage. Of nine patients with ulcers of the greater curvature, six had ulcers in the antrum and three in the middle portion. There were two deaths attributable to the lesions, and important complications occurred immediately prior to or during hospitalization in 45, including severe hemorrhage in 30 and perforation in 12. Surgical treatment was required in 21 for reasons other than suspected carcinoma. Small benign ulcers are important clinically because of the danger of serious complications.

Fires and Explosions in Hospitals.—Investigation of fires and explosions is difficult, since many institutions are reluctant to give information because of legal entanglements and pending court action. However, an effort was made to review as many as possible of such accidents that occurred in hospitals in the 11 year period from 1938 to 1949. This investigation does not include those reported by Greene in 1941. Questionnaires were sent to all hospitals registered with the American Medical Association in 1948. There were 2,285 replies (35.7%) from 6,400 hospitals. In this group 28 fires and 41 explosions in operating rooms were reported. The commonest cause was static electricity (32 cases), while suction pressure machines and cautery apparatus were the second and third commonest causes. Since static electricity caused 32 of 41 explosions, these 32 cases are analyzed. The operating room had no conductive flooring in 24 (75%) of the cases. There was no grounding in 17 (59.3%) cases. In the light of recommended safe practices for operating rooms, these are extremely high percentages. Sparks from a mask as it was removed, woolen blankets, woolen trousers, rubber-soled shoes, silk slips, sponge rubber cushion on anesthetist's stool, and nonconductive linoleum flooring caused some of the explosions. Explosions due to static electricity occurred most frequently during the last and first quarters of the year. It is estimated that about eight explosions per year due to static electricity occur in hospitals in the United States. Conductive flooring, grounding, and proper clothing are still not used in many hospitals, and this situation should be corrected.

*Surgical Therapy of Acute and Chronic Arterial Occlusion. J. W. Lord Jr.—p. 259.

Surgical Therapy of Arterial Occlusion.—The four cases of acute arterial occlusion may be classified as embolic, thrombotic, traumatic, and spasmodic. In the embolic cases, an embolectomy is generally indicated in patients under 50, if they are seen within 10 hours of onset, if the artery obstructed is the aorta, iliac or femoral artery, and if the general condition of the patient is such that an operation is tolerable. Embolectomy is generally contraindicated for emboli of the upper extremity and of the lower extremity from the popliteal artery down. The use of heparin broadens the indications for embolectomy as far as the age and time factors are concerned. The ideal management of the patient with an acute thrombotic occlusion of a main artery is still conservative and nonoperative. For acute arterial occlusion due to trauma, the best period for repair is between two and twelve hours after the accident. Methods available for repair are direct suture, autogenous vein graft, or homologous arterial graft. The spasmodic type of acute arterial occlusion, seen most frequently with massive venous thrombosis of the lower extremity, is handled best by Veal's method of vigorous passive and active exercise of the leg, with elevation. The surgical therapy of chronic arterial occlusion should be limited to selected cases after failure of nonoperative measures. Only sympathectomy seems to have real therapeutic value in properly selected cases. The surgical procedures discussed by the author are (1) the so-called revascularization of the leg by production of a three-limbed arteriovenous fistula; (2) the operation of "scraping" the thrombosed artery; and (3) the resection of a relatively short segment of the thrombosed artery, followed by insertion of an autogenous vein graft to restore blood flow through the main arterial channel. Finally the author describes a new surgical treatment of occlusion of the subclavian or axillary artery that is due to disorders of the shoulder girdle. The operative procedure consists of total subperiosteal resection of the clavicle followed by removal of the periosteum, division of the scalenus anticus muscle, and mobilization of the subclavian artery. Good early results were obtained with this method in eight patients with shoulder girdle syndromes of hyperabduction, scalenus anticus, and costoclavicular, or cervical rib syndromes that had resulted in temporary occlusion or permanent thrombosis of the artery.

*Culdoscopy. S. T. Lee.—p. 294.

Culdoscopy.—The culdoscope is an instrument for visualization of the female pelvis through the cul-de-sac. It was designed by Decker and Cherry, when attempts to visualize the pelvis through the peritoneoscope were unsatisfactory because of intervening bowel and difficulty in isolating the pelvic organs. A special trocar and cannula are necessary to perforate the cul-de-sac for introduction of the culdoscope. The importance of performing the procedure in the knee-chest position to utilize the negative pressure produced to draw air into the abdomen and thus push the bowel out of the pelvis has been repeatedly stressed by Decker. On the basis of his own experience with culdoscopy in 45 cases, Lee concludes that cul-de-sac puncture for introduction of a culdoscope is easily made with the patient in the knee-chest position. The pelvic organs can be viewed clearly. In all cases in which laparotomy was done after the examination, the culdoscopic diagnosis was confirmed. In no case in which tubal pregnancy was present was the diagnosis missed in culdoscopic examination. Patients were only slightly uncomfortable after the examination. No pelvic peritonitis resulted in any patient, and no pregnant patient aborted as a result of the procedure.

Pulmonary Infarction Following Cardiac Catheterization.—The major complications of cardiac catheterization are cardiac arrhythmias, which develop largely as a result of introduction of the catheter into the right auricle and ventricle, and thrombosis at the venotomy site that sometimes propagates centrally. To measure the pulmonary "capillary" pressure, Houssay and associates introduced the catheter by the usual fashion into the pulmonary artery and then advanced it further until it was wedged into one of the distal branches of this vessel. In the first 100 cases in which this procedure was employed, no untoward reactions occurred, but in March, 1950, the first of a series of pulmonary infarctions occurred in a patient with mitral stenosis and congestive heart failure. At first, these infarctions occurred only sporadically, but later they occurred with increasing frequency. Between March and November of 1950, only four such infarctions occurred; between November, 1950, and May, 1951, pulmonary infarcts were produced in 15 of 27 patients with mitral stenosis. In no instance did death occur, but many of the patients had a stormy course for several days. The pulmonary infarction occurred from 2½ to 79 hours following wedging of a cardiac catheter into a branch of the pulmonary artery. In other patients without pulmonary congestion, pulmonary infarction did not occur. When the catheters were sterilized by autoclaving instead of by soaking in mercuric oxycyanide, pulmonary infarction did not occur in 20 consecutive patients with either severe mitral stenosis or congestive heart failure. Thus there seems to be no doubt that chemical sterilization of the catheters was responsible for the infarction.

Enhanced Virulence of Candida Albicans by Aureomycin.—The author describes studies of the mechanism of the stimulation of growth and increase in pathogenicity of fungi sometimes observed in patients treated with antibiotics. The strain of Candida employed proved to be nonpathogenic for mice on intraperitoneal injection of large amounts of cells (320 million) in saline. The aureomycin dose of 2 mg. intraperitoneally was also nontoxic. However, when Candida cells were suspended in aureomycin solution (0.1 ml. of cells in 2.4 ml. of aureomycin) and the mixture injected intraperitoneally, 16 of 17 mice died in one experiment and 28 of the 32 died in another. A similar though less pronounced "drug-fungus" effect was observed when aureomycin was given from 24 hours before to 4 hours after Candida inoculation. Aureomycin given 8 to 24 hours after infection was ineffective. The virulence-enhancing activity of aureomycin was destroyed by standing at room temperature or by boiling. No indication of toxin production or biological alteration of Candida was found in vitro. No direct growth-stimulating effect by aureomycin on Candida was observed in cultures. The action in vivo was one of lowering the animal's resistance.

Production of Mental Changes by *d*-Lysergic Acid Diethylamide Tartrate.—The chemical *d*-lysergic acid diethylamide tartrate (L. S. D.) belongs to the ergonovine group of ergot alkaloids. This paper describes the mental changes produced by *d*-lysergic acid diethylamide tartrate in 17 experiments on 15 volunteers. Besides such subjective symptoms as change in appetite, poor co-ordination, and nausea, changes were observed in thinking and speech, emotion, mood, affect, sensory and time perception, and behavior; there were also morbid ideas and sensory experiences and neurological signs. The reaction occurred in three phases lasting a total of from 12 to 16 hours; in some subjects a fourth phase, lasting one to several days, was seen. The reaction showed some aspects of an exogenous toxic picture. Even more impressive, however, was the simulation of schizophrenic manifestations. Simple schizophrenic and turmoil states were common. Transient paranoid trends were frequent. Schizophrenic symptoms such as negativism, ambivalence, blocking, and unexplained smiling were observed. Schizoaffective and manic-like states were also encountered. Catharsis was experienced by only one subject. The reaction was not specific, and the extent to which it was dependent on the basic personality of the subject was not determined. The clinical effects imply involvement of the highest centers of the central nervous system and perhaps of lower levels of the nervous system as well. Further study of this drug is indicated because of the remarkable simulation of schizophrenic and affective psychoses on oral administration of a very small amount of this substance.

*The "Best" Method of Prostatectomy. H. M. Gibson Jr.—p. 138.

The "Best" Method of Prostatectomy.—Four surgical approaches to the prostate, the suprapubic, transurethral, perineal and retropubic, are described. The disadvantages, results, and special indications for each method are considered. It is apparent that there is no "best" method of prostatectomy. In general, any one of the methods properly carried out will give satisfactory results in most cases. The method selected by the individual surgeon will depend on his training, inclinations, equipment, and hospital facilities. However, in certain cases, the favorite operation of a surgeon will not give the best results; when this happens, he must be able to adapt the one best suited for the patient. It is no longer sufficient for the urological surgeon or the general surgeon who does prostatectomies to know and perform only one method. In order to give the maximum benefit to the patient, he must learn all four methods.

Ligation of Inferior Vena Cava for Pelvic Thrombophlebitis.—Follow-up studies are reported on 70 patients who had undergone ligation of the inferior vena cava and ovarian vessels for suppurative pelvic thrombophlebitis between Feb. 2, 1942, and January, 1950. Ligation was performed only if the patients had failed to respond to medical therapy or showed evidence of pulmonary infarction and had severe pelvic infection. Sixty-two of the 70 patients survived. All patients who died within one year of operation were considered operative failures, because the authors feel that ligation accomplishes nothing if the patient dies of distant septic metastasis, even though the vena cava and ovarian vessels are successfully ligated. Four of the eight patients who died were operated on from 9 to 21 days following admission to the hospital, and the authors feel that in these death did not result from delay in operating. Varicosities of the abdominal wall, flank, thigh, or legs did not develop in any of the patients. One woman had varicosities of the legs prior to operation, but they were not made worse by ligation of the inferior vena cava and ovarian vessels. Forty-eight of the patients had no edema. Eight patients noticed occasional mild swelling of the feet after they had been up and about for many hours. Six patients noted some swelling of the ankle and lower half of the leg to about the calf except when at complete bed rest. None of these patients were incapacitated. The vascular status of some of the patients was evaluated, and provided evidence that there was adequate compensation for the ligation of the vena cava. Subsequent surgical procedures required by some of the patients disclosed that the operative hazard was not increased. Menstrual or sexual function was not altered by ligation of the inferior vena cava and ovarian vessels. The authors conclude that ligation of the inferior vena cava and ovarian vessels is indicated in patients with suppurative pelvic thrombophlebitis who fail to respond to medical therapy. Ligation can be done at the same time as other surgical interventions.

Carcinoma of Thyroid and Nontoxic Nodular Goiter.—At the Ochsner Clinic 51 proved cases of carcinoma of the thyroid were compared with 529 cases of nontoxic nodular goiter. The incidence of carcinoma discovered at operation was 19.8% in glands with single nodules, and 12.8% in glands with multiple nodules. In the cases of carcinoma, the average interval between discovery of the tumor and institution of definitive treatment was 5.7 years and between the discovery of the tumor and the time the thyroid was first examined by a physician was 2.8 years. The diagnosis of carcinoma was not made clinically in 63.4% of the cases and was not made at operation in 39% of the cases. In the nine cases of "lateral aberrant thyroid" in which the homolateral lobe of the thyroid was removed, the primary carcinoma was found in the lobe in each instance. The admittedly short term follow-up revealed that about 60% of the patients in the present series are apparently well, and about 17% are dead as a result of the neoplasm. The surgical treatment for carcinoma of the thyroid at the Ochsner Clinic is individualized, but generally hemithyroidectomy with removal of the isthmus is performed on patients whose tumor is limited to the thyroid. If the lesion has spread to the cervical nodes, or locally to muscles, or if there is evidence of local recurrence, radical neck dissection is performed. Patients with massive involvement are best treated by removal of as much tissue as possible, decompression of the trachea, tracheotomy, and postoperative roentgen therapy. The authors stress the following points: 1. Carcinoma of the thyroid cannot be diagnosed early by present clinical means. 2. The incidence of carcinoma in both single and multiple nodular goiters is sufficiently high to warrant prophylactic thyroidectomy for all nodular goiters unless a definite surgical contraindication exists. 3. "Lateral aberrant thyroids" are in reality metastases in cervical lymph nodes and should be so treated.

*Effect of Streptomycin on Tuberculous Lesions of the Lung. P. Golard. —p. 29.

Effect of Streptomycin on Pulmonary Tuberculous Lesions.—Limitation of pulmonary lesions by fibrous walling-off is a histological reaction characteristic of primary infection. Lung specimens from persons with a severe primary infection treated with streptomycin show a somewhat more pronounced tendency toward walling-off, and the caseous foci are not so pronounced as in untreated patients. These changes are the morphological expression of the body's defensive reaction against infection facilitated by the bacteriostatic effect of the antibiotic. Streptomycin seldom arrests a serious primary infection completely. The best indication for streptomycin treatment occurs in recent miliary infection; signs of anatomical cure have been found in patients who died of other causes after having been treated for miliary tuberculosis. Most of the tubercles show hyperplasia of the lymphocytic elements; structural changes also occur in the central epithelioid cells, forming central lacunae that enlarge as a result of giant cell degeneration. Centripetal lymphocytic proliferation gradually fills the lacunae, making the tubercles predominantly lymphoid. The lymphoid tubercle undergoes hyalinization; the cells accompanying it are resorbed, and only nonspecific fibrous formations are left in the place of the initial lesion. Streptomycin accelerates the natural healing process in chronic miliary lesions, reducing the seriousness of the disease and making it susceptible to other methods of treatment. Streptomycin action on bronchial tuberculous lesions is more rapid and intense than on those in the lungs, and its effects vary with the localization of the lesion in the mucosa or the deeper layers of the tissues. Exudative phenomena are favorably influenced; perifocal reactions decrease and limitation of the lesions is accentuated. Streptomycin, however, has little or no effect on caseous nodules. Parietal cleansing, resorption of exudate, and evacuation of casein are the principal advantages of streptomycin in the treatment of cavities; collapse therapy is usually needed to complete the cure. The rapid and frequent appearance of nonspecific cicatrices, rarely seen in the spontaneous development of tuberculosis, is a characteristic effect of streptomycin therapy.

Insulin Hypoglycemia in Rheumatoid Arthritis.—Several investigators have observed clinical remissions in patients with rheumatoid arthritis after treatment with insulin hypoglycemia. Godlowski and Paterson report studies on 10 women who had had rheumatoid arthritis for from a few months to 18 years. In all of the women the onset was associated with the beginning of menopausal symptoms, and none had had rheumatic fever or rheumatoid arthritis previously. Before, during, and after treatment the body weight, blood picture, and urinary output of 17-ketosteroids, 11-oxycorticoids, creatinine, and uric acid were determined. Insulin hypoglycemia was induced by giving the fasting patient at 8 a. m. a subcutaneous injection of insulin. The doses varied between 20 and 80 units, but were sufficient to produce the clinical symptoms of hypoglycemia. The hypoglycemic attack was interrupted by means of a glassful of sugared water and a meal rich in carbohydrates. The insulin hypoglycemia was repeated daily for from 14 to 28 days. Nine of the 10 patients showed significant improvement during and for some time after treatment, but all relapsed during the succeeding 10 months, and in some the disorder progressed more rapidly than before treatment. Thus insulin hypoglycemia only temporarily retards the course of this type of rheumatoid arthritis.

Familial Incidence of Rheumatoid Arthritis.—The familial incidence of rheumatoid arthritis and acute rheumatism was compared in 100 patients with rheumatoid arthritis and 100 controls. The incidence of these diseases was 5.3% in the families of patients and 2.3% in the families of controls when grandparents, parents, uncles, aunts, brothers, and sisters were included. The incidences were 11% and 4.6% respectively in the two groups when only parents, brothers, and sisters were included. From these figures it was concluded that approximately one-third of patients with rheumatoid arthritis will have a family history of rheumatoid arthritis or acute rheumatism in two or more members (as many as 7 affected members were recorded in one family of 16); approximately one-third will give a history of one affected member; and the remaining one-third will have no relatives with these diseases. It is suggested that there is a tendency toward development of acute rheumatism or rheumatoid arthritis in certain families. This constitutional tendency is discussed in relation to Selye's "general adaptation syndrome" and Kendall's view that a hypersensitivity state may underlie rheumatoid arthritis. As regards the former, certain persons may have a hereditary weakness in their adaptation mechanism; as regards the latter, it is suggested that certain persons may have a constitutional tendency to react to the effects of the products of an antigen-antibody reaction through the medium of the synovial membranes.

Limit of Renal Tolerance to X-Rays.—After orchiectomy has been done for seminoma of the testis, the region of potential metastases includes the aortic iliac and inguinal lymph nodes and the associated lymphatics. In prophylactic treatment of this region x-rays are commonly employed in a dose of from 2,000 to 3,000 r in three to six weeks. If the kidney is included in the field of irradiation, renal damage may occur. This report is based on a study of over 30 cases. Such damage may be unrecognized unless it is specifically looked for. There is usually a latent period of several months before the onset of symptoms, which in the cases here reported averaged eight months. The first complaints were dyspnea on exertion, headache, swelling of the ankles, and lassitude. On examination pallor was noted. Edema was usually present, but varied in extent and severity. The blood pressure was increased in all cases at some time. In some patients the retinas showed hemorrhages, exudates, and papilledema, and the clinical picture then suggested malignant hypertension. Cardiac enlargement, pulmonary edema, and hepatic enlargement due to congestion were all found in the more advanced cases. Severe dyspnea was a troublesome symptom. Anemia usually progressed rapidly. All patients had albuminuria, and in the urine of some granular and hyaline casts were found. Some of the patients died within a few months of the onset of symptoms, death being due to chronic uremia or to left ventricular failure. However, considerable improvement was possible even in severe cases following judicious blood transfusions and prolonged rest. Those who survived the initial more acute symptoms had signs of chronic nephritis, such as albuminuria, hypertension, anemia, increased blood urea levels, and impaired renal function. The various techniques that were employed for the prophylactic roentgen irradiation of these patients had been described previously, but in this paper an account is given of the arrangement of the fields and the basis on which the dosage is calculated. The survival rates in 93 cases and the incidence of renal failure are correlated with the distribution of the dose through the kidneys. In patients in whom renal failure developed, one entire kidney or both kidneys had received a dose of 2,000 r or over in five weeks. The "safer" techniques were characterized by smaller doses to the upper poles of both kidneys. The risk of renal failure may best be minimized by insuring that about one-third of the volume of the kidneys is outside the irradiated fields or is irradiated with as small a dose as possible. Renal function and location should be determined before roentgen treatment of the abdomen is undertaken.

Cortisone in Asthma.—Mitchell and Cameron studied 21 patients with intrinsic bronchial asthma who had been given courses of cortisone or cortisone and corticotropin combined. The duration of asthma varied from a few months to 49 years; four patients had had attacks for less than two years. The severity of the asthma varied from case to case, but in most cases it was of the severe intractable type, with decreasing response to bronchodilators. Seventeen of the patients were given cortisone by the intramuscular or oral route; two were given corticotropin for the first two days in conjunction with cortisone therapy; one was given corticotropin after several days of cortisone therapy while the cortisone dosage was gradually decreased, and one was given corticotropin after an initial unsatisfactory trial of cortisone. The authors gained the impression that cortisone has a definite role in treatment of patients with intrinsic bronchial asthma whose emphysema is not severe enough to cause irreversible changes in their lung fields. It may be a lifesaving measure in patients in status asthmaticus who do not respond to bronchodilators; this is demonstrated in the three cases. The response to the drug is more or less unpredictable. Many more cases should be studied before its value in asthma can be assessed. Cortisone was found to be just as effective orally as intramuscularly. Oral doses of 200 mg. for one day, and then 100 mg. daily for several days thereafter were sufficient. Relapse usually occurred from one week to three months after cortisone had been discontinued. Maintenance doses have to be continued. Cortisone should only be tried in patients in whom all other forms of medication have failed. Side-effects were not frequent. One patient has been taking cortisone for 10 months without ill effect.

Experiences with Para-Aminosalicylic Acid.—The combined use of *p*-aminosalicylic acid orally and streptomycin intramuscularly in patients with pulmonary tuberculosis has become standard practice. In this study one group of 221 patients received only 1 gm. of streptomycin daily for from 60 to 90 days. Organisms persisted in 154 of this number, and in 67% the bacilli showed increased resistance. In a second group 58 patients received 1 gm. of streptomycin and 2 gm. of *p*-aminosalicylic acid daily for the same period. Orangisms persisted in 30 patients, and 64% of these after cessation of therapy had organisms with increased resistance to streptomycin. A third group of 146 patients received 1 gm of streptomycin and 10 gm. of *p*-aminosalicylic acid daily for 60 to 90 days. In 72 cases organisms persisted and 18% of these patients had organisms with increased streptomycin resistance. Thus it would seem that a daily dose of 10 gm. of *p*-aminosalicylic acid rather than 2 gm. along with 1 gm. per day of streptomycin caused a marked reduction in the number of streptomycin-resistant strains of tubercle bacilli.

*Spinal Block During Streptomycin Therapy of Tuberculous Meningitis. P. Nicolaj.—p. 39.

Spinal Block in Streptomycin Therapy of Tuberculous Meningitis.—A severe complication that may occur during streptomycin therapy of tuberculous meningitis is spinal block. This may occur when the streptomycin dosage is inadequate or it is given only intramuscularly thus inhibiting but not stopping the process, whose slow development leads to spinal block. It may be attributable to local irritation resulting from excess streptomycin administered intrathecally, predisposition of the patient to this complication, or a general allergic reaction to the antibiotic. In patients who were never treated with the drug spinal block may arise either because the process develops slowly, or because the meningeal exudate concentrates around the first part of the spinal cord, obstructing the circulation of the fluid. The author reports on 12 patients, in three of whom spinal block developed before treatment was instituted. In four it resulted from inadequate streptomycin therapy, in four from local irritation by the antibiotic, and in one as a part of a general allergic reaction to the antibiotic after recovery from meningitis. It was more frequent in adults than in children, and as a rule, symptoms were severer in patients who had not received streptomycin or only inadequate doses of it. The spinal fluid in all patients was xanthochromic and showed excess albumin. Six patients died, including all four in whom streptomycin therapy had been *inadequate. It is suggested that the prognosis is more favorable in patients who are not treated with streptomycin before the onset of the spinal block and in those in whom the block was caused by local irritation from the antibiotic. If therapy, which must be individualized, is adequate, the spinal block may recede completely, as in some of the author's patients, with complete restoration of all the functions that had been impaired.*

Pituitary Tuberculoma. L. C. Oliver.—p. 698.

Self-Demand Feeding in a Maternity Unit.—A flexible feeding schedule favors the development and maintenance of successful lactation. Babies have been shown to demand very frequent feedings from the fifth to the eighth day of life; when they are kept waiting on a rigid schedule they are apt to become tired and to swallow air as a result of crying, making suckling difficult. The relation of the feeding schedule to the establishment of lactation was studied by feeding one group of 106 babies on a rigid schedule and another group of 131 on a self-demand schedule, beginning on the third day, and comparing the two groups in regard to weight gain, incidence of overdistention of the breasts in the mothers, and incidence of breast-feeding on discharge and at the age of one month. All babies were fed at six hour intervals during the first two days for fear that more frequent feeding might cause soreness of the nipples. Then babies in the demand group were fed when they wanted it, day or night; the others were fed every four hours by day and once at night (6 feedings in 24 hours). Demands from babies in the demand group were most frequent between the fourth and seventh days, 36 babies demanding 8 feedings or more on the fifth day, and 12 demanding 9 or more. Babies fed on demand gained weight more rapidly than the others; by the ninth day 49.1% had regained their birth weight as compared with 36.1% of those on the rigid schedule. Test feedings, showing a positive correlation between the weight gain and the amount of milk taken, indicated that babies fed on demand empty the breast better than those on a rigid schedule. Overdistention of the breast and soreness of the nipples was more than twice as frequent among mothers of babies on a rigid schedule as among mothers of babies in the demand group. The number of fully breast-fed babies in the rigid group declined from 88.1% at the time of discharge to 64.5% at the age of 1 month. Comparable figures for the demand group were 94.4% on discharge and 80.3% at 1 month. Self-demand breast-feeding, by causing better emptying of the breast and less frequent soreness of the nipples, favors lactation.

*Copper in Treatment of Hypochromic Anemia Refractory to Iron. S. I. de Vries.—p. 611.

Decreasing Mortality from Whooping Cough in Nursing Infants.—Minkenhof and van der Kooi gained the impression that during the last 50 years infant mortality from whooping cough has decreased not only as the result of more spontaneous recoveries but also because of more effective treatment of secondary pneumonia. Furthermore chloramphenicol and aureomycin do not influence uncomplicated whooping cough favorably. On the contrary, they found that in some cases these drugs render other bacteria, such as those causing pyoderma, resistant to all chemotherapeutic and antibiotic drugs. However, secondary bronchopneumonia that has proved resistant to sulfonamides, penicillin, and streptomycin responds favorably to these drugs. Investigating the deaths among 249 infants with whooping cough who had not been immunized against this disease, the authors found that while in 1946 there were 22 fatalities among 56 cases, there were none among 40 in 1951. Secondary pneumonia was treated with sulfonamides or dihydrostreptomycin. Aureomycin was used and proved effective in only two resistant cases. Since 1948, infants with whooping cough have been given dihydrostreptomycin in order to prevent pneumonia.

Copper in Treatment of Hypochromic Anemia.—De Vries reviews the literature on the use of copper in the treatment of anemia. On the basis of his own observations on eight patients, of which four are reported in detail, he is convinced that, in patients with hypochromic anemia who are refractory to treatment with iron and in whom the copper content of the serum is low, treatment with copper will have a therapeutic effect. It is assumed that copper has a catalytic effect in these cases.

*Simmond's Syndrome Treated with Desoxycorticosterone Acetate, Testosterone Propionate and Thyroidin and with ACTH. H. Petersen. —p. 351.
*Vitamin B_{12} Treatment of Megalocytic and Macrocytic Anemia. J. S. Baastrup.—p. 356.

Treatment of Simmond's Syndrome.—Simmond's syndrome must be differentiated from myxedema, Addison's disease, and anorexia nervosa; myxedema is the most frequent mistaken diagnosis. In the first case reported no treatment was attempted because of the unfavorable prognosis. In one of the three patients treated with desoxycorticosterone acetate (percorten®), testosterone propionate (perandren®) and iodothyrin ("thyroidin") the result was particularly good and in another case the results were good from the somatic viewpoint, but the psychic changes were not affected. During this treatment attention must be directed to such symptoms of overdosage as increase in weight, increase in blood pressure, edema, and signs of cardiac insufficiency. In the cases described slight signs of overdosage were seen in the form of crural edema, increased weight, and increased blood pressure. *In the third case in which the combined treatment was used unsuccessfully, treatment with corticotropin (ACTH) had had no effect.* The commonest causal factors in Simmond's syndrome were represented, craniopharyngeoma in one case, grave postpartum hemorrhage in two cases; the etiology in the remaining case is unknown. Petersen's impression is that possibly psychic changes cannot be influenced favorably by treatment.

Vitamin B_{12} Treatment of Megalocytic and Macrocytic Anemia.—Seven cases of pernicious and related anemia were treated by intramuscular injection of vitamin B_{12}. In one case of pernicious anemia, one case resembling pernicious anemia, and two cases of macrocytic anemia complete remission resulted, while in two cases of pernicious anemia and one case resembling pernicious anemia the hemoglobin level and the erythrocyte count rose only to slightly subnormal values. Since injection treatment with vitamin B_{12} is agreeable for the patient and since in some cases complete remission follows and in other cases the treatment at least to begin with is as effective as treatment with liver and stomach preparations, it seems to Baastrup reasonable at present *first to try treatment with vitamin B_{12} in megalocytic and macrocytic anemia; if full restitution is not attained, liver and/or stomach preparations can be given, perhaps with the addition of vitamin B_{12}.*

BOOK REVIEWS

The Metabolic Response to Surgery. By Francis D. Moore, M.D., Moseley Professor of Surgery, Harvard Medical School, Boston, and Margaret R. Ball, A.B. Publication number 132, American Lecture Series, monograph in American Lectures in Surgery. Edited by Michael E. De Bakey, M.D., Professor of Surgery, Chairman of Department of Surgery, Baylor University College of Medicine, Houston, and R. Glen Spurling, M.D., Clinical Professor of Surgery, University of Louisville, Louisville, Ky. Cloth. $7.50. Pp. 156, with 48 metabolic diagrams by Mildred B. Codding, A.B., M.A., Surgical Artist, Department of Surgery, Harvard Medical School, Peter Bent Brigham Hospital, Boston. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 49 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto, 2B, 1952.

This book describes studies carried out on metabolic balances in order to determine the biologic responses to surgery. The studies deal with patients undergoing surgery who had been treated by ordinary methods. A uniform method of charting is presented, and, although an attempt has been made to present it simply, it has become cumbersome and confusing as can be noted in figure 31 on page 83. Charting of this type, although accurate and conclusive, must be simplified if it is to be of practical value, particularly to the general practitioner or the general surgeon.

Great detail was gone into in the preparation of this material, and the authors utilized a "team" of 35 co-workers. Careful studies were made on total intake and total output of selected chemical substances in order to cast light on biologic processes. The collection of output presented special problems. When dressings were stained by exudate or gastrointestinal contents, they were either soaked in distilled water or put through a small washing machine with distilled water, and this water was analyzed for nitrogen and electrolytes. Operative blood loss was measured calorimetrically, utilizing acid hematin on sponge rinsings; this was checked by total nitrogen.

This book is not easy to read. The need for profound study detracts from its practicability; however, it is a sincere study and may be of reference value as further studies dealing with these metabolic responses are carried out. The two most appealing sections are those dealing with facts and corollaries and surgical diet and parenteral supplements.

Child Psychiatric Techniques: Diagnostic and Therapeutic Approach to Normal and Abnormal Development through Patterned, Expressive, and Group Behavior. By Lauretta Bender, B.S., M.A., M.D., Professor of Clinical Psychiatry, New York University College of Medicine, New York. Cloth. $8.50. Pp. 335, with 55 illustrations. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 49 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, 1952.

The author of this volume is well known for her work on the psychology of perception and her "visual motor Gestalt" test, which is used extensively by psychologists. In this book Dr. Bender describes the technique she uses in treating psychiatric conditions of childhood. The work is based on the results obtained in the reexamination of thousands of problem children at the psychiatric division of the Bellevue Hospital. Some of these children were first examined when they were very young and were reexamined during adolescence. Parts of the book were published previously but are now unified. Some of the work was done with other authors, notably the late Paul Schilder.

The book will be of great value to psychiatrists, psychologists, and play therapists, but it will also be of interest to the general physician. Some chapters will be of special value to pediatricians, notably the ones on form as a principle in the play of children, the drawing of a man by children with chronic encephalitis, the art of high grade mental defective children, and group activities on a children's ward. Although the book is technical, the author's style is simple. The illustrations, many of which are freehand, add to the value of the book.

American Universities and Colleges. Mary Irwin, Editor, American Council on Education. Sixth edition. Cloth. $10. Pp. 1105. American Council on Education, 1785 Massachusetts Ave., N.W., Washington 6, D. C., 1952.

American Junior Colleges. Edited by Jesse P. Bogue, Executive Secretary, American Association of Junior Colleges. Third edition. Cloth. $7.50. Pp. 604, American Council on Education, 1785 Massachusetts Ave., N.W., Washington 6, D. C., 1952.

"American Universities and Colleges" contains full descriptive data on 904 accredited universities and colleges in the United States, Alaska, Hawaii, and Puerto Rico. The new feature in this edition is the arrangement of institutions by states, with an institutional index instead of the former alphabetical listing by name only.

Part 1 of the book is devoted to professional education. Discussion on medical education by Dr. D. G. Anderson, Secretary of the American Medical Association Council on Medical Education and Hospitals, is concluded by a list of accredited medical schools. Dentistry, pharmacy, nursing, and veterinary medicine are adequately discussed.

The companion book, "American Junior Colleges," contains descriptions of 575 accredited junior colleges in the United States. This list is also arranged by states, with data on R. O. T. C. units and other features. These two publications are indispensable reference tools in any library, college, or office concerned with higher education.

The United States Public Health Service 1789-1950. By Ralph Chester Williams, M.D., Assistant Surgeon General, United States Public Health Service, Washington, D. C. Cloth. $7.50. Pp. 890, with illustrations. Commissioned Officers Association of United States Public Health Service, Box 5874, Bethesda, Md., 1951.

This excellent history of the United States Public Health Service is well written, carefully documented, and impressive in its scope. The author is a regular career officer of the service, with broad experience in many different departments of the service. The presentation is effective, the typography good, and the photographic material of unusual historical interest.

The dramatic role of the Public Health Service in protecting the American people from communicable disease introduced from other countries is particularly well told. The innumerable other health activities, curative, educational and preventive, are also described at length in an interesting and stimulating fashion. The United States Public Health Service emerges from this history as a noble career service, dedicated to preserving the health of the people within the framework of the policies adopted by Congress and singularly free from the political storms that have afflicted many other federal agencies. If the author fails to note and record the occasional policy errors and internal dissensions that must have occurred some time in the long history of the United States Public Health Service, he may be forgiven, for the total story is true, an exciting, fruitful history of physicians devoted to public service in the finest tradition of medicine.

Atlas of Genito-Urinary Surgery. By Philip R. Roen, M.D., F.A.C.S., Instructor in Urology, New York Post-Graduate Medical School, New York. Introduction by Clarence G. Bandler. Cloth. $8. Pp. 325, with illustrations by Charles Stern. Appleton-Century-Crofts, Inc., 35 W. 32nd St., New York 1, 1951.

As indicated by the title, the author has compiled, with the aid of an excellent artist, a series of line drawings illustrating most of the common operations performed on the genitourinary system. The text, which describes each operation, is brief and direct, often being less than half a page in length, and is placed on the page opposite the illustration to which it refers. There is an illustration on every other page of the book. The book was planned for the resident, the young urologist, and the general surgeon who is occasionally required to perform a urologic operation. Only standard surgical procedures are discussed, although, in some cases, multiple procedures are illustrated for a given type of operation. Details of surgical technique are not

---

The reviews here published have been prepared by competent authorities and do not represent the opinions of any official bodies unless specifically stated.

included, but the principles and successive steps of a given operation are outlined.

The book is divided into nine sections dealing respectively with general principles of urologic surgery, operations on the kidney, adrenal gland, ureter, bladder, prostate, scrotum and testicles, and urethra and penis. An index is included. The author draws from his experience in learning, teaching, and practicing urology for his discussion of the essentials of standard urologic operations that he has found useful and practical. The material is discussed in an easily understandable form, with clear illustrations and a minimum amount of text. The book is neither a textbook for the medical student nor a reference book, as no bibliographic references are included, and descriptions of many less common procedures are omitted, but it should be a useful manual for those not too familiar with urologic surgery. Although not everyone would agree with certain practices suggested by the author, such as the use of oxidized cellulose gauze imbedded in the renal parenchyma and the use of carbolic acid in surgical treatment of solitary renal cyst, his opinions, in general, coincide with current urologic practice. Indications for and relative evaluation of various surgical procedures are not included. The book is beautifully and completely illustrated and provides a quickly available source of information pertaining to urologic surgery.

Symposium über die Beeinflussung des reaktiven Geschehens durch Hypophyse und Nebennierenrinde. Veranstaltet von der Schweizerischen Akademie der medizinischen Wissenschaften 30. September bis 2. Oktober 1951 in Zürich. [In German, English and French.] Sonderausgabe von Fasc. 1/2, Vol. 8 des Bulletin der schweizerischen Akademie der medizinischen Wissenschaften. Paper. 16 Swiss francs. Pp. 228, with 75 illustrations. Benno Schwabe & Co., Klosterberg 27, Basel 10; imported by Grune & Stratton, Inc., 381 Fourth Ave., New York 16, 1952.

This monograph consists of a series of 20 papers on the effects of cortisone and corticotropin (ACTH); they were read at a meeting of the Swiss Academy of Medicine at Zürich in September, 1951. The first 12 papers deal with tissue reactions, the next 2 with hemorrhagic states, and the last 7 with allergic reactions and their influence. They are written in English or German, depending on the nationality of the author, and there are brief discussions by participants at the symposium at the end of each paper. Almost all the material is based on the authors' own work, which by now has been published through the usual channels. Those interested in the experimental field will find this collection valuable, particularly the criticisms and comments of the discussants. Like similar collections that have appeared elsewhere, the work throws light on the fundamental mechanism of action of corticotropin and cortisone. The papers deal with such diverse topics as the effect of cortisone on trichophytosis in guinea pigs (Sonck and Miescher), the relation of the endocrine system to tissue reactions in tuberculosis (Rössler), the effect of cortisone on the tuberculin reaction (Ballabro and Sala), the Arthus phenomenon (Uehlinger), its site of action (Studer), and its relation to anaphylaxis (Dougherty). Of more clinical interest are papers dealing with corticotropin and cortisone therapy of asthma (Rose), ulcerative colitis (Weissbecker), and eczema (Miescher).

Today's Science and You. By Lynn Poole, Producer of Johns Hopkins TV Science Review. Cloth. $2.75. Pp. 208, with illustrations by Jeanne Bendick. McGraw-Hill Book Company, Inc., 330 W. 42nd St., New York 18; Aldwych House, Aldwych, London, W.C.2, 1952.

Many of the discussions in this small volume seem to offer little in the way of helpful education. This may be because the discussion does not relate the various scientific advances closely enough to what the average man knows. For example, it will not profit a man much to know that there is a device capable of seeing 100,000 colors, that the perfect fly repellent has yet to be developed, or that different shaped knobs on the automobile panel can simplify car operation. These and other scientific findings reported are interesting but open to so many arguments that their value may be questioned. Nevertheless, there is a considerable amount of interesting material. Anyone who has watched the Johns Hopkins Science Review on television will agree that many extremely stimulating programs have been presented. Perhaps the lesson from this is that science teaching can be effective only when it is given in the real-life pattern for which television is unique.

The Diagnosis and Treatment of Intrathoracic New Growths. By Maurice Davidson, M.A., D.M., B.Ch., Consulting Physician to Brompton Hospital for Consumption and Diseases of Chest, London. With chapter on Radiotherapy by David W. Smithers, M.D., M.R.C.P., D.M.R., Professor of Radiotherapy, University of London, and chapter on Operative Treatment by Oswald S. Tubbs, M.A., M.B., B.Chir., Thoracic Surgeon to St. Bartholomew's Hospital, London. Cloth. $8.75. Pp. 260, with 170 illustrations. Oxford University Press, 114 Fifth Ave., New York 11; Amen House, Warwick Sq., London, E.C.4, 1951.

As a rule, when a senior British physician produces a volume on a clinical subject, one can expect a clear, readable, and balanced presentation. This monograph is no exception. The author brings his extensive clinical experience to bear on a topic that is of immense practical importance today. The point of view is that of the general physician who, encountering tumors of the chest in his practice, is seeking reliable information in regard to the present methods of treating them. The material is discussed according to pathological entity. Each tumor or class of tumors is discussed according to its morbid anatomy, clinical diagnosis, and treatment. This is not, however, merely a handbook of differential diagnosis or a manual of diagnostic tests but a careful description of pathological processes supported by well-documented and pertinent clinical examples.

A large portion of the book is devoted to carcinoma of the bronchus. The discussion is that of the intelligent physician's point of view toward surgery of the lung. Surgical treatment is measured against radiation therapy and chemotherapy. The latter are discussed at length together with excellent practical advice for the treatment of the "untreatable" patient.

The chapter on mesoblastic growths provides an account of pleural endothelioma and related tumors. The confusing aspects of this problem are well illustrated by specific examples. Separate chapters on the techniques of radiation therapy, by Smithers, and standard thoracic surgical procedures, by Tubbs, complete the volume.

This book can be highly recommended as an intelligent correlation of fundamental pathology and wide clinical experience. It should be of great service both to the general practitioner and his expert consultant. It should provide excellent background material for medical students and residents and should find a place in any well-equipped hospital library. The text is delightfully written, and the illustrations are superb.

Fractures and Joint Injuries. Volume I. By Sir Reginald Watson-Jones, B.Sc., M.Ch.Orth., F.R.C.S., Orthopædic Surgeon to His Majesty the King, London. Fourth edition. Cloth. $22 per set. Pp. 443, with 709 illustrations. Williams & Wilkins Company, Mount Royal and Guilford Aves., Baltimore 2, 1952.

In every era of medicine, certain select treatises have profoundly influenced medical education and practice. Sir William Osler's "Textbook of Medicine" is an outstanding example. In the field of traumatic surgery, Sir Reginald Watson-Jones' "Fractures and Joint Injuries," the first volume of the fourth edition of which has recently been published, is another.

The first edition of this important textbook was published in 1940, at the beginning of the great conflict that was shortly to engulf mankind. It described clearly and concisely the principles underlying the treatment of fractures and joint injuries, and it can be said that, perhaps more than any other surgical text of our time, it became the "bible" of surgeons in every land, confronted as they were then by a host of complicated orthopedic injuries. It raised the standards of treatment incalculably, and untold thousands owe life, limb, and happiness to its author. Since 1940, successive editions have been published, each in its turn revised and rewritten to incorporate the experience gained by Sir Reginald in his unique vantage point as civilian consultant in orthopedic surgery to the Royal Air Force and more recently as director of the orthopedic and accident service at the London Hospital.

The fourth edition has been carefully revised to include recent advances in the treatment of fractures and joint injuries, and many new illustrations have been added. The physiology and pathology of bone repair are carefully and wisely discussed, and the all-pervading principles of treatment stressed. In chapter 6, there is a valuable discussion of vascular injuries, immersion foot, frostbite, and the crush syndrome. In the discussion of nerve injuries in chapter 7, the Seddon and Cohen classification of nerve injuries is retained, but perhaps a more venturesome policy of earlier nerve exploration and repair would seem justified with the present advantages of chemotherapeutic control of infection. The section on clinical and radiographic diagnosis is of great value and should be read and reread by all practicing surgeons.

A wise and balanced conservatism governs the author's advice on the operative reduction of certain fractures, and, in the present volume, the great value of intramedullary nailing of certain fractures, notably of the femur, is commented on. The chapter on reactions of bone to metal is a most welcome addition to the present edition. It stresses that the use of plates, screws, and nails are merely methods of internal suture, which, in fact, introduce foreign bodies not unlike sequestra. This is an important observation that may well temper our present and perhaps premature advocacy of prosthesis in the treatment of avascular necrosis of the head of the femur and osteoarthritis of the hip joint.

A new and valuable addition is the chapter on shock, stress, and the adaptation syndrome, the invariable complications of all major injuries. The discussion and advice tendered is sound and practical. The section on open fractures and joint injuries has been greatly enhanced in value by important sections on the chemotherapeutic control of infection, the early closure of wounds by secondary suture or skin grafting, and the role of plastic surgery in fracture treatment. Few procedures are more important, and, until recently, more neglected. The last chapters of the book deal with fatigue and stress fractures, birth fractures, and pathological fractures. They are of immense value, and perhaps nowhere else has so much recondite information been so clearly assembled.

The plates and illustrations are excellent throughout, demonstrating clearly the author's discussion. The style is clear, straightforward, and to the point. The type is easily read and the paper used of excellent quality. In addition, the book is of manageable proportions. This book is a fine achievement, worthy of its distinguished author and of British surgery.

Lehrbuch der Röntgendiagnostik. 5. und 6. Lieferungen: Innere Organe. Von H. R. Schinz, W. E. Baensch, E. Friedl, und E. Uehlinger. Nebst Beiträgen von E. Brandenberger et al. Fifth edition. Paper. 84 marks; 98 marks. Pp. 1921-2356, with 522 illustrations; 2357-2884, with 507 illustrations. Georg Thieme, Diemershaldenstrasse 47, (14a) Stuttgart O; agents for U. S. A., Grune & Stratton, Inc., 381 Fourth Ave., New York 16, 1951; 1952.

For the review of sections 1 to 4 (*J. A. M. A.* 144:885 [Nov. 4] 1950; 146:1542 [Aug. 18] 1951) this reviewer had access to a privately owned copy of the fourth edition, but the edition available at his own institution and the one generally available in the United States is the third and, in the present review of sections 5 and 6, comparisons, of necessity, are between the third edition published in 1932 and this fifth edition published nearly 20 years later.

These two sections contain 962 richly illustrated pages dealing with the thorax in health and disease and will be followed by still more material on the cardiovascular system as a part of section 7. The space devoted to the normal thorax has been doubled and now includes a consideration of microfilming, a detailed description of the technique of bronchography with water soluble contrast media, and a consideration of normal lung architecture as seen in bronchograms.

The pages dealing with nontuberculous diseases of the trachea, bronchi, and lungs have been expanded from 91 in the third edition to 354 in the fifth. Particularly noteworthy are the passages on congenital anomalies of the bronchi and the appearance of the bronchial tree in various types of bronchitis. Aspirated foreign bodies, pulmonary neoplasm, and the various pneumonias are adequately discussed and illustrated, and in addition to the so-called dust diseases the authors include a description of the findings following aspiration of aqueous and nonaqueous fluids and the inhalation of gases. For the mycotic pulmonary diseases the authors have turned largely to the American literature. Lung cysts, lung abscesses, and parasitic diseases of the lung are discussed and well illustrated. The story of pulmonary tuberculosis, which was told in 72 pages in 1932, takes up 113 pages in the new edition. One hundred and eighty pages are devoted to diseases of the pleura, diaphragm, and mediastinum, and these are followed by 27 pages of tables and sketches summarizing the criteria for the differential diagnosis of pulmonary disease.

The final 215 pages of section 6 are given over to the roentgen findings in the normal and diseased heart, pericardium, and great vessels, and this same subject will be continued as part of section 7, which is to follow. In 1932, 116 pages were considered adequate for this subject, but radiology has made great strides in 20 years. Much of the added material is concerned with angiography, a subject that was barely mentioned in 1932.

It is hard to conceive of a textbook of radiology more complete or more dependable than this magnificent fifth edition, which reflects so well the enormous development that has occurred in clinical radiology within two decades. In 1932, three authors plus six collaborators sufficed, but today four authors and 13 collaborators are required. The authors remain authors, however, and not mere editors, so that one finds a completeness, unity, and minimum of repetition that is apt to be lacking in a compilation by a group of individually competent contributors.

Einführung in die Röntgenologie: Ein Lehrbuch für Ärzte und Studierende. Von G. F. Haenisch, a. o. Prof. Dr. med., Chefarzt i.R. am allgem. Krankenhaus Barmbeck, Hamburg, und H. Holthusen, o.ö. Prof. Dr. med., Chefarzt am allgemeinen Krankenhaus St. Georg, Hamburg. Mit einem physikalisch-technischen Beitrag. Von A. Liechti. Fifth edition by W. Fehr. Cloth. 60 marks. Pp. 521, with 371 illustrations. Georg Thieme, Diemershaldenstrasse 47, (14a) Stuttgart O; agents for U. S. A., Grune & Stratton, Inc., 381 Fourth Ave., New York 16, 1951.

The chief authors of this extensive introduction to roentgenology are well known to Americans. This edition is greatly expanded beyond the first edition of 1933. There are 44 pages devoted to physical and technical background, and the section on diagnosis, by Dr. Haenisch, is 240 pages long. The second half of the book, by Holthusen, is a masterly exposition of the field of roentgen and radium therapy. Radioactive isotopes are fully described, and growth disturbances following gamma irradiation are discussed and illustrated. This is an area that has been neglected in American literature. Delayed or late damage to the skin and internal organs receives extensive attention as does irradiation sickness. The field of superficial and deep therapy is covered with a staccato brevity and yet a thoroughness that is characteristic of Holthusen as Americans know him. For a textbook on an introduction to roentgenology, Haenisch does not seem to have spared an area of useful exposition and illustration. One cannot escape the recollection of the story of the German who, in a prize competition on the elephant, offered three volumes entitled, an introduction to the study of the elephant. The authors have compressed their contribution into one volume, apparently without missing any single important segment of roentgenology. The quality of paper, the contrast in the lithographs, and the quality of the printing surpass the average, comparable, American textbook.

Contractor's Final Report on Artificial Arm and Leg Research and Development Covering the Period January 2, 1945, to December 31, 1950. Submitted by Northrop Aircraft, Inc. Contract number VAM-23062. National Research Council Committee on Artificial Limbs Advisory to Veterans Administration and the Office, Surgeon General, United States Army. This report compiled and written by Gilbert M. Motis. Cloth. Pp. 358, with illustrations. Northrop Aircraft, Inc., Northrop Field, Hawthorne, Calif., 1951.

This report is a detailed technical description of the application of modern engineering principles and materials to the problems of increasing the functional efficiency of the prosthesis and its attachment to the amputee. The design of many devices by Northrop engineers was facilitated by basic data derived from time and motion studies of arm and leg improvement made by the University of California at Los Angeles and the University of California (Berkeley). This work will serve as a valuable reference book to those concerned with the manufacture and fitting of prosthetic units and will be a stimulus for further research.

There is an interesting chapter on x-ray cinefluorographic technique and a short appendix on an experimental infant prosthesis. Northrop has produced a good upper extremity prosthesis that satisfies all basic maker's requirements and standard prerequisites of light weight, durability, comfort, and ease of operation. There are numerous detailed drawings and photographs of the prosthetic units, their component parts, and of the attachment of these units to the amputee. This represents a distinct advance in the mechanism of artificial limbs, and the book may be read with interest by those who are interested in the problems of amputees.

Clinical Applications of Recreational Therapy. By John Eisele Davis, Sc.D., Chief, Corrective Therapy, Veterans Administration, Washington, D. C. *Publication number 123, American Lecture Series, monograph in American Lectures in Physical Medicine.* Edited by W. A. Selle, Ph.D., Professor of Biophysics, University of California Medical School, Los Angeles. Cloth. $3.75. Pp. 118, with 21 illustrations. Charles C Thomas, *Publisher,* 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 49 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto 2B, 1952.

The author of this monograph attempts to supply a basic philosophy for the employment of "free play, exercise, and activity" in rehabilitation, especially from the viewpoint of psychodynamics. The 44 sections are distinct essays that usually take some previous publication as a text. Such topics as the psychological appeal of free play and recreational techniques based on concepts of milieu therapy are discussed.

This book is mainly concerned with the rehabilitation of patients institutionalized for psychiatric purposes. The number of these patients is increasing. The effects of institutional life on their initiative can be deadly, and many are not interested in doing anything that would be useful to others or to themselves. Even so, some readers will feel that this book unduly emphasizes recreational as distinguished from occupational therapy. The meticulous, expensive forms of recreational therapy suggested need not only be rationalized on the basis of theory but must also be defended on the basis of more practical considerations. With respect to the latter, the book leaves something to be desired. It must, however, be commended, as it is well written and attractively illustrated.

Fertility in Men and Women: The How and Why of Having Children. By James Alan Rosen, M.D., Attending Obstetrician and Gynecologist, Lincoln Hospital, New York. Edited with introduction for Health Series by Harry Swartz, M.D. Cloth. $3. Pp. 177. Coward-McCann, Inc., 210 Madison Ave., New York, 1952.

This little book is the first of a projected health series, under the general editorship of Dr. Harry Swartz. This volume is prepared for the lay reader, particularly those couples who have infertility problems. The author discusses the anatomy and physiology of the male and female reproductive apparatus and the techniques and methods used in diagnosing the contributory defects. There are chapters on treatment to alleviate the complaint and an attempt at evaluation of artificial insemination as a mode of treatment in infertility problems. The information offered is technically sound and should be clear to the lay reader, but the chapters lack the style and clarity of other recent books offered to the laity. The author includes a chapter of typical case histories, which might have some usefulness but suffer from lack of professional detachment and objectivity. The format of the book is attractive. The two illustrations are crudely designed. A useful glossary of technical terms is appended.

Handbook of Basic Microtechnique. By Peter Gray, Ph.D., D.I.C., Head, Department of Biological Sciences, University of Pittsburgh, Pittsburgh. Cloth. $3. Pp. 141, with 57 illustrations. Blakiston Company (Division of Doubleday & Company, Inc), 1012 Walnut St., Philadelphia 5, 1952.

This is intended as a useful handbook for the student or technician faced with the problem of preparing animal or plant material for microscopic examination, and supplements Gray's "Handbook of Basic Microtechnique," a larger reference work now in preparation. It is an inexpensive book for quick consultation on microtechnical procedures. Part 1, devoted to materials and processes of slide making, has chapters on materials and equipment, fixation and fixatives, stains and staining, dehydrating and cleaning, mounts and mountants, making whole mounts, making smears, making sections, and cleaning, labeling, and storing slides. Part 2, devoted to specific examples of slide making, has 15 short chapters on the preparation of whole mounts, bacterial stains, and certain histological sections. This handbook meets its objectives in full and is recommended to students or technicians engaged in histological procedures.

Symposium on Geographical Pathology and Demography of Cancer. Council for Coordination of International Congresses of Medical Sciences under auspices of World Health Organization and United Nations Educational, Scientific and Cultural Organization, session held at Regent's Park College, Oxford, England, July 29 to August 5, 1950. Chairman: Prof. J. H. Maisin. Editor: Dr. J. Clemmesen. Cloth. Pp. 152, with illustrations. The Council, 19, Ave., Kléber, Paris 16^e, [n.d.].

This volume contains the papers read at a symposium held in Oxford, England, in 1950, under the chairmanship of Prof. J. H. Maisin and sponsored by the World Health Organization (WHO) and the United Nations Educational, Scientific, and Cultural Organization (UNESCO). Several papers are devoted to statistical variations in cancer incidence between different countries or within a single country. A paper by R. Doll on the etiology of cancer of the lung, especially the correlation between incidence among tobacco smokers and nonsmokers is a careful statement of current English studies. Other papers analyze cancer incidence in India, Indonesia, and North Africa in relation to nutrition and food habits, environment, and other disease states. Dr. Symeonidis from the National Cancer Institute introduces interesting observations on the relationship of poststarvation gynecomastia in Greece to hormonal imbalance and its implication as a factor in breast cancer. The administrative aspects of geographic pathology as now being developed at the National Cancer Institute are described by H. L. Stewart. Cancer demography is emerging as a definite field, and the contributors to this symposium have indicated the scope and range of investigations now developing in this field in a most effective manner. Discussions by members of the conference are included for each chapter. Each paper has an abstract in both French and English. The volume is well printed, and the graphs and charts are clear and legible. The microphotographs are poor.

Elsevier's Encyclopædia of Organic Chemistry. Founded by E. Josephy and F. Radt. Edited by F. Radt. Series III, Carboisocyclic Condensed Compounds. Volume 14, Supplement: Tetracyclic and Higher-Cyclic Compounds Except Steroids and Triterpenes. [Cumulative index]. Cloth. $88; $77 to subscribers to series III; $66 to subscribers to complete work. Pp. 938 S; 113. Elsevier Press, Inc., 402 Lovett Blvd., Houston 6, Texas; 118 Spuistraat, Amsterdam, Netherlands, 1951.

Volume 14 in the regular series of this work covered the literature on tetracyclic and higher cyclic compounds up to and including 1936. The growth of studies on these compounds has been so rapid since that time that the editors have published a supplement that brings the literature up to 1946. The amount of work done on these substances in that 10 year period has increased to the extent that it is necessary to publish the supplement in two volumes. The first of these two volumes is now available and covers all tetra and higher cyclic compounds with the exception of the steroids and triterpenes, which will appear in the second volume.

The subject index includes references to both the main volume and the supplement, with a compilation of all substances that fall into this chemical class under such index headings as carcinogenic compounds, estrogenic compounds, and naturally occurring compounds in coal tar, minerals, and plants. Such features as a summary table of the carcinogenic activities of 1,2-benzanthracene derivatives is included. The physiological properties of many interesting parent compounds and their more important derivatives are discussed. Among those discussed in the present supplement are fluoranthene, naphthacene, benzanthracene, dimethyl-benzanthracene, chrysene, benzophenanthrene, pyrene, dibenzofluorene, cholanthrene, 20-methyl-cholanthrene, dibenzanthracene, benzopyrene, and hypericin.

Contractura isquémica de Volkmann. Por F. Bastos Mora. Cloth. Pp. 119, with 44 illustrations. Publicaciones médicas José Janés, editor, Muntaner 316, Barcelona, 1951.

This is a detailed, well-written monograph that covers the subject thoroughly. The author has evidently drawn from extensive experience with this condition. The pathogenesis and pathology of Volkmann's contracture are discussed in detail. The complete clinical picture from the time of initial injury to the final tendon transplant is discussed clearly, concisely, and adequately. Alternative methods of surgical reconstruction are also discussed. The illustrations are satisfactory and the bibliography good. This work will prove exceedingly useful to those interested in Volkmann's contracture.

QUERIES AND MINOR NOTES

ALLERGY AND DUODENAL ULCER

To the Editor:—*Is allergy still recognized as a cause of duodenal ulcer? Can food allergy aggravate an existing duodenal ulcer?*

M.D., Ohio.

Answer.—A discussion of allergic factors in the pathogenesis of duodenal ulcer by Andresen and Grossman may be found in the book entitled "Peptic Ulcer" (edited by Sandweiss, D., Philadelphia, W. B. Saunders Company, 1951). It is clear, as the result of a wide variety of experimental studies, that allergic reactions can be produced in the mucous membrane of the stomach or the duodenum very much as they can be produced in the skin. For the most part, however, they heal readily and do not give rise to chronic, progressive ulcers resembling those seen in man or those produced in experimental animals either by the Mann-Williamson procedure or by the transplantation of the antrum of the stomach into the colon by the method of L. R. Dragstedt and his associates. Andresen believes that an allergic response to some of the products arising in the body as a result of foci of infection may produce typical ulcers and may also cause their recurrence. He suggests that the beneficial effects of removal of foci of infection may in part be due to these factors. Most of the experimental and clinical evidence at present available indicates that duodenal and gastrojejunal ulcers are due to the corrosive properties of the gastric content that are greater than normal because of hypersecretion of gastric juice in the fasting stomach as well as after the ingestion of food. This hypersecretion is thought by Dragstedt to be of nervous origin, and this is the basis for the vagotomy operation.

CEPHALIN FLOCCULATION TEST IN HEPATITIS

To the Editor:—*Is information available on the length of time a cephalin flocculation test remains positive after a patient is clinically free from hepatitis?*

F. A. Nause, M.D., Sheboygan, Wis.

Answer.—It is difficult to give a categorical answer to this question without knowing the technique of the cephalin cholesterol flocculation test performed. As a general rule, the test becomes negative at or about the time the serum bilirubin returns to a normal figure. This was the general experience with volunteers and has been confirmed many times in studies on the naturally occurring form of the disease. In a recent study m the army hepatitis center in Germany, only 10% of 667 tients studied had a positive cephalin cholesterol flocculation st by the end of the fourth week of the disease when the 48-hour flocculation test was used. When the 24-hour flocculation test was used, the percentage of positive tests at the end of the fourth week was more than twice as high. By the end of the third month of the disease, only about 2% of the 48-hour flocculation tests were still positive (Neefe, J. R.; Gambescia, J. M.; Gardner, H. T., and Knowlton, M.: Comparison of the Thymol, Cephalin-Cholesterol Flocculation and Colloidal Red Tests in Acute Viral Hepatitis, *Am. J. Med.* 8:601 [May] 1950).

Sborov and Keller have recently presented figures on patients with the mildest form of the disease: 74% of patients with serum bilirubins of less than 5 mg. per 100 cc. had negative cephalin flocculation tests by the third week of the disease. In patients who had serum bilirubins at a higher level a much higher incidence of positive tests was obtained. In general, one ay say that a patient who has a positive cephalin cholesterol occulation test, which persists beyond the third month from the onset of jaundice, deserves investigation by other methods to be certain that subacute or chronic hepatitis is not developing.

LUMBAR MENINGOMYELOCELE

To the Editor:—*I repaired a lumbar meningomyelocele on a 1-day-old infant. The surgical procedure was uneventful, and the child has done reasonably well. Two weeks later, a neurosurgeon who examined the child said the repair should not have been done, because it was unnecessary and the removal of a sac from which fluid might be absorbed would cause hydrocephalus. We have had, in our hospital, about six of these infants in the last two years. None of them were treated surgically, and hydrocephalus developed in all of them. It is difficult for me to understand how absorption of fluid from the spinal canal (arachnoid) could, in any way, affect an internal hydrocephalus and why repair of a meningomyelocele would have anything to do with the development of hydrocephalus. What is the proper treatment of a lumbar meningomyelocele without skin covering?*

M.D., Texas.

Answer.—The selection of patients with lumbar meningomyelocele who can be surgically treated must of necessity be on an individual basis. The surgeon should elect to operate only on those patients whom he believes he can help. The fact that it is surgically possible to repair the defect on the back is not, in itself, sufficient indication for operation. Children whose legs are paralyzed, who have a loss of sensation in the sacral distribution, who have a paralysis of bowel and bladder, or in whom a hydrocephalus is developing, are not suitable candidates for surgical repair of the deformity.

There is no good evidence that removal of the meningocele sac is responsible for the development of hydrocephalus. On the contrary, the study of a large number of cases has shown that hydrocephalus develops as frequently if the meningocele is not operated on. This is not surprising, because pathological studies demonstrate that the abnormality responsible for the hydrocephalus lies in the head and not in the spinal canal. It is true that the idea that the sac absorbs cerebrospinal fluid has been advanced, but it has not been generally accepted nor is it in accord with the facts.

If a congenital deformity of this nature is suitable for surgical repair, the redundant skin and meninges should be excised, the dura mater should be closed tightly, and fascial flaps should be reflected from the paravertebral muscles on both sides and imbricated over the defect in the spinal canal. The skin is then closed. No attempt should be made to close the bony defect.

LIVER BIOPSY

To the Editor:—*Please tell me the technique used for obtaining a needle biopsy specimen of the liver.*

J. C. Eakle, M.D., Sutton, W. Va.

Answer.—Liver biopsy can be performed to advantage with the "vim"-Silverman needle, a 14-gage needle having a hypodermic bevel tip. It contains an inner needle that is split longitudinally and has a cutting edge. After preparation of the skin and a preliminary dose of morphine sulfate, a small nick is made in the skin, usually at the right midclavicular line, just below the costal margin. The outer needle is inserted with the inner needle withdrawn, so that its point is above the bevel of the outer needle. The inner needle is then moved forward into the substance of the liver.

As it advances, it cuts out a small cylinder of liver tissue, about 2 mm. in width. The outer needle is then advanced over the inner needle, thus trapping the specimen, closing the prongs of the inner needle, and separating the innermost portion of the tissue to be removed. Both needles are then withdrawn simultaneously. The small specimen of tissue obtained, usually measuring 2 cm. by 2 mm., is, as a rule, adequate for a study of liver histology.

Most operators confine their biopsies to patients who have hepatomegaly and in whom the subcostal approach is possible;

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any official bodies unless specifically stated in the reply. Anonymous communications and queries on postal cards cannot be answered. Every letter must contain the writer's name and address, but these will be omitted on request.

however, many who are more experienced do not hesitate to obtain specimens through the ninth intercostal space in the posterior axillary line. The risk of the procedure is relatively small, provided one avoids the danger of bleeding. Bleeding, coagulation, and prothrombin times should be determined routinely on all patients for whom liver biopsy is contemplated. If there is any evidence of there being an inflammatory process within the abdomen or at the right lung base, the procedure is contraindicated. About 5% of patients have some pain postoperatively; this usually disappears within a few hours. There is an excellent account of the various instruments and techniques used in an article by Hoffbauer (*J. A. M. A.* **134**:666 [June 21] 1947).

MILD CONVULSIVE SEIZURES IN INFANT

To the Editor:—*A primipara delivered a child easily following an uneventful pregnancy. An episiotomy was performed, but forceps were not used. The child at birth weighed 9 lb., 12 oz. (4,422.52 gm.) and seemed to be normal. About two and one-half months after birth, mild convulsive seizures developed in the child. During bottle-feeding or when he is lying at ease in the crib, he suddenly has clonic contractions of the arms and legs, with inconstant horizontal nystagmus. The first attack lasted about 30 seconds; subsequent ones have been less severe. After the first two attacks he cried loudly and long and then quieted down and was apparently normal. During the seizures he turns pale and appears to lose consciousness to varying degrees. During the first two attacks, the baby seemed to have colic. Recently, he has had a mild upper respiratory tract infection and had the last few attacks with the onset of the infection. The child has been examined by several pediatricians, all of whom gave the opinion that he is normal. An electroencephalogram was made by a neurologist, who reported normal results. The child eats well. I would appreciate a discussion of the etiology, treatment, and prognosis of this condition.*

Edgar E. Struve, M.D., Fullerton, Calif.

Answer.—With the normal birth history and normal results of physical examination, it seems reasonable to rule out birth injury as a cause for these attacks. Infantile tetany could be excluded as a cause by the rarity of its occurrence before the age of three months and by the lack of a history of rickets or of an abnormal condition observed during physical examination. The existence of a normal blood calcium level would eliminate the possibility of infantile tetany, as would normal reactions to electric stimulation. Parathyroid tetany is a rare condition caused by hypofunction of the parathyroid. When noted in infancy, it occurs in the period immediately after birth and is characterized by a low blood serum calcium level. Tetany may also be associated with alkalosis caused by vomiting and loss of acid gastric secretions, by hyperventilation, by the administration of salts that form insoluble calcium compounds, and by nephritis with chronic renal insufficiency, in which the level of inorganic phosphates of the blood serum rises and the level of blood serum calcium falls. In the case in question it is assumed that the results of urinalysis are normal and that no nephritis is present. These conditions include most of those that have a physical etiological basis and, from the data furnished, can probably be quite easily excluded from possibility.

Some functional conditions may give rise to the symptoms shown by this infant. Occasionally, an infant shows unusual susceptibility to many kinds of stimuli, and has prolonged spells of crying and muscle spasms causing flexion of the arms and legs and clenching of the hands. He is easily startled, frequently thrashes about, and may evidence breath holding and pallor; such a baby is termed a hypertonic infant. In the past, these babies were thought to suffer from vagotonia and were often treated with atropine. The exact pathogenesis of this condition is not clear, although heredity probably is an important factor. These infants respond favorably to hospitalization or the substitution for their care of a calm nurse for easily agitated parents. Mild sedation with phenobarbital sodium for several weeks is often helpful. The prognosis is generally good: the symptoms usually subside completely, and permanent emotional instability is not a necessary aftermath of this condition.

HYDROCEPHALUS AND SPINA BIFIDA

To the Editor:—*A child, who had mild hydrocephalus and severe spina bifida but was apparently normal otherwise, weighing 6 lb. and 15 oz. (3.15 kg.), died five days after birth. This was the mother's third pregnancy and her first son. Two other children are normal. The mother is one of three children, all girls, the first of whom had a congenital defect of the spine, described by the grandparents as typical of mild spina bifida. The mother also had two half-sisters, neither of whom had any congenital defects. There is no history of congenital defects in her husband's family. Are hydrocephalus and spina bifida definitely hereditary? If so, what were the chances of this child being affected, since two others were normal? What are the chances of a fourth or fifth child being normal? Could the mother's health during the third pregnancy have influenced the appearance of the defects? (She suffered from hypothyroidism, fairly well controlled by thyroid extract, 4 grains [0.25 gm.] daily, mild hypoglycemia, and moderately severe secondary anemia.) Does the sex of the child influence the likelihood of congenital defects of this type?*

M.D., Georgia.

Answer.—Ordinarily, neither hydrocephalus nor spina bifida is definitely hereditary. Spina bifida, with visible deformity on the back, such as a meningocele or a meningomyelocele, occurs in about one out of every thousand births. Spina bifida occulta, which is usually asymptomatic and often without external manifestation, occurs in about 5% of the population. This is in addition to spina bifida of the lowest sacral segments, which occurs in practically everyone. Occasionally, instances of congenital defects in the spinal column, associated with deformities of the nervous system, have shown a definite hereditary or familial tendency. In the present instance, the history, as given, is not sufficiently detailed to permit one to judge whether there is a familial tendency present here. The nature of the congenital defect said to have been present is not stated nor are we certain of the presence of congenital defects in some members of this family. In view of the inadequate information on these points, positive statements beyond those given above are not possible. The cause of the congenital deformities of the spine in persons in which they appear is unknown. It is conceivable that the mother's health could be a factor. Whatever the cause, it must be effective within the first month of intrauterine life. After that date, the development of the nervous system has proceeded to such a point that this type of deformity would not be possible. There is little evidence that sex of the child influences this type of congenital deformity. The matter is fully discussed in P. C. Bucy's "Spina Bifida and Associated Malformations" (in Practice of Pediatrics, edited by J. Brennemann, Hagerstown, Md., W. F. Prior Company, Inc., 1937, vol. 4, chap. 15.)

TREATMENT OF PAIN IN ARTHRITIS

To the Editor:—*Two products in tablet form have come to my attention for the treatment of rheumatoid arthritis. One contains p-aminobenzoic acid and the other, sodium gentisate. I am interested in knowing which drug has proven more effective in alleviating the pain of rheumatoid arthritis.*

Francis M. Walker, M.D., Rochester, N. Y.

Answer.—Sodium gentisate was reported in 1948 to be as effective as salicylates in relieving articular pain in rheumatoid arthritis; however, it possesses no special advantages over salicylate preparations, except that it may be tolerated in a patient who is unable to take either aspirin or sodium salicylate. *p*-Aminobenzoic acid, in common with other benzoates, exerts some analgesic action, although inferior to that gained from salicylates. About five years ago, its use in conjunction with sodium salicylate was studied. The conclusion was drawn that the blood salicylate level was thus increased, chiefly by means of decreasing the excretion of free salicylate. Determinations made subsequently have failed to confirm these findings, although a clinical study has shown that an enhanced analgesic effect may be obtained by the addition of *p*-aminobenzoic acid to oral doses of sodium salicylate. In the experience of many who treat rheumatoid arthritis, aspirin is more consistently effective than sodium salicylate in relieving pain and stiffness and is therefore the drug chosen. Sodium salicylate may be substituted for patients who show gastric intolerance to aspirin in any form.

EFFECTS OF DIAGNOSTIC RADIATION

To the Editor:—*In several cases of apparently highly radiosensitive tumors, after routine initial diagnostic roentgenologic work-up (chest x-ray examination, gastrointestinal series, or urological radiographs), the hematological picture has shown an increase in hemoglobin, red blood cells, and thrombocytes, without any medication or change in food intake. Can it be that in the initial phase of the disease, the small dose of roentgen radiation thus incurred and directed unknowingly at the suspected cancer was effective in causing secondary hematopoiesis by inhibiting growth of the mass and metastases or in stimulating primary hematopoiesis?*

C. D. J. Generales, M.D., New York.

Answer.—It is likely that the amount of radiation received in certain diagnostic procedures can produce recession of highly sensitive malignant tumors, but it does not seem possible that the blood changes described could be due to a primary or direct effect on the hematopoietic system. The cells of the hematopoietic system are highly sensitive to radiation, but the effect of the latter is to produce destructive, rather than productive, changes. Neither does it seem probable that a destructive effect on a primary tumor or its metastases could produce the stimulative effect described. It seems more likely that the improved blood picture in the observed cases is either coincidental or due to improvement in the patient's general health.

ESTROGENS AND CANCER OF THE UTERUS

To the Editor:—*A 49-year-old patient with adenocarcinoma of the uterus and metastasis was elsewhere put on estrogen because of nervousness and other symptoms following bilateral ovariectomy. I am treating her with deep x-ray therapy, but I am not following the doctor's instructions about giving her estrogen, as I am a little skeptical, regardless of her menopausal symptoms. Is there definite proof that the administration of estrogen under these circumstances is a hazard?*

M.D., Alabama.

Answer.—There is no definite evidence that estrogens are carcinogenic. In spite of this inconclusive evidence, it is the opinion of a number of gynecologists that it would be better to withhold the hormone in patients who have carcinoma or who have had it. Cancer of the endometrium is not found frequently in the castrate, and Dockerty reports that prolonged, unopposed estrogen stimulation may be a factor in the production of such endometrial changes. Therefore, the usual menopausal symptoms in a woman of this age would best be controlled either with sedation or with the male hormone, testosterone.

PHARMACOLOGY OF MAGNESIUM SULFATE

To the Editor:—*Please summarize the pharmacodynamics of magnesium sulfate as related to its use in the treatment of toxemias of pregnancy. What, if any, are its toxic effects on the body? In three instances we observed gross hematuria after intramuscular injection of 10 to 20 cc. of 50% magnesium sulfate, and we are reasonably sure that bleeding did not occur from an indwelling catheter present at the time. Is it possible for a chemical nephritis to have occurred?*

W. R. Fallon, M.D., Chicago.

Answer.—Magnesium sulfate is used in the treatment of preeclampsia and eclampsia because of its sedative and vasodilator effects. These pharmacologic actions favor a decrease in the blood pressure and allay the convulsive seizures. The efficacy of the drug as a central nervous system depressant and as a vasodilator has been substantiated by experimental as well as clinical evidence. It is considered the most efficient drug for allaying the convulsions of tetanus. It has been used extensively in the treatment of hypertension and uremia because of its vasodilating effects. Haury has shown that the intravenous injection of magnesium sulfate produced marked dilatation of the splanchnic organs and the kidneys.

Magnesium sulfate is a respiratory depressant, and, when used in any dosage, it is prudent to have an antidote readily available in the form of a 10% solution of calcium chloride or calcium gluconate. Calcium salts should be administered slowly if the patient has been digitalized. Hematuria following the administration of magnesium sulfate has not been reported. The amount administered to this patient is not excessive, for as much as 35 gm. has been given to a patient during the first 24 hours of eclampsia without undue effects.

THE SCLERA IN CAROTENOSIS

To the Editor:—*Can hypercarotenemia produce yellowish pigmentation of the sclera as well as of the skin? If so, which appears first and why? Is there any relationship to jaundice?*

Max S. Lake, M.D., Salina, Kan.

Answer.—The yellow pigmentation of the skin known as xanthosis, or carotenosis, is caused by an excess of carotene in the blood and is most marked in the palms, soles, and nasolabial folds. In contrast to jaundice, the scleras usually remain clear. The differential diagnosis of xanthosis and jaundice depends on the history and other findings, a knowledge of the patient's diet, the concentration of bilirubin in the serum, the icterus index and the lipochrome index. When with yellow pigmentation of the skin a low value for the serum bilirubin and a high icterus index are present, the condition must be xanthosis; if the value for the serum bilirubin is high and the lipochrome index is low, the abnormal coloration is due to jaundice. If both the concentration of serum bilirubin and the lipochrome index are elevated, xanthosis and jaundice are associated.

TREATMENT OF SMALL AREA OF DRY GANGRENE ON ARM

To the Editor:—*Advice is requested regarding the treatment of of an area of dry gangrene. The area is situated on the volar, medial aspect of the left upper forearm and is about 1 in. (2.54 cm.) by 1½ in. (3.81 cm.) in size. This condition developed after the paravenous injection of a small amount of 10% calcium levulinate. The black, dry, necrotic crust is sharply demarcated from the unaffected skin, which does not show any inflammatory reaction. On palpation, the underlying tissues and possibly the muscle appear to be affected by the necrotic wedge. There is no pain, but use of the left forearm is somewhat impaired.*

M.D., South Dakota.

Answer.—This necrotic lesion should be treated conservatively. In most instances, the necrotic area will slough off, and healing will take place spontaneously. If, after several months, this does not occur, surgical excision may be necessary, and granulation will then probably fill in the defect.

ACTIVITY AFTER OPERATION FOR UTERINE PROLAPSE

To the Editor:—*After a plastic operation for complete prolapse of the uterus, how soon can the patient be out of bed? How soon can she do heavy work, and how soon can she have sexual intercourse?*

M.D., Central America.

Answer.—The pattern of postoperative care has changed markedly in recent years. There is no reason why the patient cannot be allowed out of bed to the bathroom or to use a bedside commode the day after surgery. Early ambulation is desirable, because many of the patients are elderly and early activity decreases the hazards of thrombosis and infarction. Ambulation should be restricted during the first week. Heavy work should be postponed for at least eight weeks. Sexual intercourse is permissible six or eight weeks after surgery if the healing has been satisfactory. The administration of an estrogen, such as 0.5 mg. of diethylstilbestrol, each night for three or four months after surgery favors healing and the restoration of a normal vagina in the woman in the postmenopausal period.

RECENT ADVANCES IN THE MEDICAL TREATMENT OF CIRRHOSIS OF THE LIVER

Sidney A. Portis, M.D.
and
Sylvan Weinberg, M.D., Chicago

The incidence of cirrhosis of the liver is increasing. Whereas previously it was seen mostly with alcoholism or malnutrition or as a complication of cholecystitis and cholelithiasis, physicians today are confronted with additional causative factors. The widespread epidemic hepatitis of World War II produced a sporadic inoculation of persons hitherto never exposed to the virus of infectious hepatitis. The etiological relationship of acute infectious hepatitis to cirrhosis of the liver is favored by most authors.[1]

Sulfonamides and other hepatotoxic agents have taken their toll of the liver. Aureomycin has been rather extensively used in the treatment of acute and chronic hepatitis. Recently Lepper [2] reported that, among 14 patients given large doses of aureomycin for serious infections, both by mouth and intravenously, 7 showed clinical evidence of liver dysfunction. Furthermore, necropsy in five and biopsy in one of these cases showed pathological changes in the liver cells; however, the doses of aureomycin used are now considered to be excessive.

Finally, the establishment of blood banks and the use of nonirradiated plasma have resulted in serum homologous hepatitis in some patients and have made cirrhosis of the liver a disease of serious import. No longer can one regard blood transfusions as an innocuous procedure unless the medical history of the donor is known.

GENERAL MEASURES

Certain general measures are applicable in the treatment of all types of liver disease. The recognition of the cause of the liver disease is necessary for effective therapy, and removal of the causative factors assumes a major role whenever they can be determined. In the treatment of jaundice one is constantly confronted by the immediate question of whether one is dealing with a medical or a surgical problem. It may not be amiss at this time to emphasize the importance of cholecystectomy and common duct exploration when indicated as a therapeutic measure in the treatment of liver disease. It is well established that cholecystitis usually produces hepatitis, the degree depending on the resistance of the liver on the one hand and the severity of the inflammatory process in the biliary tract on the other. We are firmly convinced that cholecystectomy should be done whenever cholelithiasis is found, in order to prevent liver damage. Certainly the morbidity and mortality of operative intervention can be markedly decreased if such operations are done before liver damage supervenes or when the liver damage has been improved by the therapeutic measures outlined above. This matter should be seriously considered unless there is a definite contraindication for operative intervention. In our experience contraindications become fewer when a careful evaluation of a surgical risk is made and scientific management is substituted for the haphazard surgical procedures previously employed.

It is preferable that the treatment be carried out in a hospital, where repeated studies of the progress of the disease may be made. When the liver damage is more than minor, it is best also to keep the patient in bed. The use of drugs should be avoided as much as possible, and it should be kept in mind that even the commonly used barbiturates and sulfonamides can impair the function of the normal liver and constitute an added strain on a damaged liver.

Constipation also is an added strain and should be treated with mild laxatives. Bile acids are preferable to bile salts because they produce choleresis and therefore decrease the viscosity of bile. Dehydrocholic acid may be used, 3 to 5 grains (0.20 to 0.30 gm.) three times a day. It not only is a laxative but helps to reduce intrahepatic bile capillary pressure. Furthermore, if the constipation is interdependent on overplay of the sympathetic nervous system and inactivity of the parasympathetic nervous system, parasympathomimetic drugs, like neostigmine (prostigmin®) and benzpyrinium (stigmonene®) bromide, stimulate the gastrointestinal tract, so that perfectly

normal bowel movements are possible without irritation of the lining of the bowel. If one prefers other preparations, however, saline laxatives, effervescent sodium phosphate, or magnesium citrate are much better for the patient than the harsher magnesium sulfate or similar drugs, which, we feel, irritate the intestinal tract too much.

DEXTROSE THERAPY

Intravenous administration of dextrose is one of the most powerful therapeutic measures in the physician's armamentarium for the treatment of liver disease. It is all-important to maintain the glycogen content of the liver cell. It is possible that hyperglycemia inhibits neoglycogenesis and results in needed rest to the enzyme systems responsible, thus contributing to faster recovery. For this, several measures are suggested. If ascites is present, one should start with concentrations of 50% dextrose in volumes of 100 to 200 cc. daily, continuing until the output of fluids exceeds the intake. After this, administration of 300 to 400 cc. of aqueous 25% dextrose solution should be continued until there is another demonstrable increase in the output of fluid, when one may use 10% aqueous dextrose solutions in volumes of 3,000 to 4,000 cc. daily. If at any time during this regimen the output of fluids is less than the intake, one may have to resort as before to use of the more concentrated solutions to restore the fluid balance.

A difference of opinion exists, however, concerning the advantages of intravenous dextrose therapy if the patient can take the "necessary" dextrose or carbohydrate by mouth.[3] The "necessary" amount of carbohydrate is that amount sufficient to raise the blood sugar to a level that will suppress hepatic sugar output. However, while the normal liver will respond to the usual postprandial hyperglycemia, associated with a high carbohydrate intake, the "irritable" liver in patients with acute toxemia may require a much higher blood sugar concentration to inhibit gluconeogenesis. That this is so is seen in the prompt curtailment by the acutely poisoned liver of its output of sugar when large doses of dextrose are given intravenously, while small doses have little or no effect.[4] Furthermore, as Cori and Cori [5] have pointed out, for the normal liver "the blood sugar concentration and not the amount of glucose administered must be regarded as important for the rate of its glycogen deposition." Consequently, when an attempt is made to protect a damaged liver by means of glycogen deposition therein, the blood sugar concentration may have to be raised to a level impossible to obtain by ingestion of carbohydrates. In such cases, the intravenous infusion of dextrose is essential. The fact that extreme hyperglycemia so produced may result in glycosuria should not deter one from such vigorous therapy. Wakim and Mann [6] have shown that regeneration of hepatic tissue after injury begins in islands of normal cells that are supplied mainly by arterial blood, while the cells in areas supplied only by portal vein blood may be too badly injured to regenerate. If the cells from which regeneration is to originate are to receive the full benefit of high dextrose concentration so that they can begin to restore liver parenchyma, the hyperglycemia following intravenous therapy is desirable.

Because of the glycosuria that may result from intravenous dextrose therapy, some physicians favor the routine use of insulin with the sugar. However, unless the patient has diabetes, the indiscriminate use of insulin may defeat the purpose of dextrose administration. Soskin, Allweiss, and Cohn [7] have shown that, in the presence of sufficient insulin to maintain a normal constant blood sugar level, no additional insulin is necessary to obtain a normal hepatic response to administered sugar. The injection of insulin into the nondiabetic person can, therefore, produce no additional hepatic effect, but it does cause increased storage of glycogen in the muscles. This peripheral effect causes a fall in blood sugar, which in turn stimulates the liver to pour out more sugar. Thus, the liver is deprived of glycogen rather than the reverse. Maintaining the hyperglycemia in spite of the administered insulin will prevent this reversal in effect but will not be more beneficial than the administration of the same amount of sugar without insulin. Soskin, Allweiss, and Mirsky [8] have shown that the use of insulin with dextrose, as compared with the use of dextrose alone, in the treatment of toxic, nondiabetic animals shortens life. After prolonged treatment by intravenous dextrose injections designed to suppress the sugar-producing mechanism of the liver, that organ requires time to recover from the inhibition of dextrose formation, so that hypoglycemia may appear one to three hours after cessation of the infusion.[9] This should be anticipated and treated with small doses of carbohydrate by mouth or intravenously if necessary. Many patients with atrophic cirrhosis and associated ascites have been definitely relieved by the daily parenteral injection of hypertonic dextrose solution, which not only is a factor in liver repair but acts as a diuretic agent. However, in patients with prolonged, overwhelming changes of the liver, this treatment may not produce as striking results as in those with early disease.

USE OF AMINO ACIDS

If the patient is unable to eat a full diet, it may be well to administer infusions of amino acids in doses adequate to maintain the normal nitrogen balance. Eckhardt and associates [10] and Lewis and co-workers [11] have questioned that hydrolyzed proteins or amino acids can be utilized normally in the presence of liver damage that may impair the deamination capacity. Eckhardt and associates [10] demonstrated that 500 to 1,000 cc. of 10% amino acid solution administered intravenously each day over a period of one-half to one and one-half hours was metabolized and excreted by patients with diseased liver in a manner differing little from normal. It was further demonstrated that, when this solution was the only source of nitrogen and lipotropic substance, clinical improvement occurred. Lewis and associates [11] and Fagin and Zinn [12] have reported similar results. A possible slight decrease in urea formation and a slight decrease in the rate of amino acid disappearance was reported in cirrhotic patients. Amino acids administered intravenously rapidly are not well tolerated either by cirrhotic or by normal persons. Evidence suggests that reactions are no more frequent in one group than in the other. Frequent side-effects include flushing, nausea, and vomiting.

VITAMIN THERAPY

The role of vitamin therapy of chronic liver disease is not entirely clear at this time. While it has become almost routine to include supplementary administration of vitamin B complex in the management of cirrhosis of the liver, definite evidence for vitamin B deficiency in cirrhosis per se has not been demonstrated.[13] Such vitamin therapy may be expected to be of value only when specific deficiency exists. Moreover, certain theoretical considerations suggest possible damage from excessive use of vitamins. For example, the administration of nicotinic acid in large doses may be harmful in the presence of fatty liver (Chalmers and Davidson [14] and Handler and Dubin [15]). A portion of this vitamin is excreted as the methyl derivative. In animal experiments this has been shown to hasten the development of cirrhosis when a deficient diet was given. A possible antilipotropic effect has been implied.[15] McHenry [16] has suggested that thiamine hydrochloride therapy under certain circumstances may promote fat infiltration in the liver. Morgan [17] has deduced from experimental work that increasing the intake of nicotinic acid of persons with multiple vitamin deficiencies may precipitate conditions worse than the subacute deficiency state produced by an inadequately balanced diet. György [18] has pointed out that it is important to include adequate vitamin B complex in the diet but that imbalance among elements of the B group should be avoided. The deduction is that massive use of any one element of the vitamin B complex is likely to be of little benefit when no specific deficiency exists and may be harmful. Cautious and specific use is therefore necessary. The role of vitamin B_{12} and its possible interrelation with folic acid, choline, and methionine have not been sufficiently explored to permit definitive comment at this time. Vitamin C administration is of value in protecting against some hepatotoxins and is used therapeutically to protect some of the enzyme systems and improve resistance of the liver cells. Vitamin A deficiency is common in liver disease because of impaired absorption resulting from bile deficiency, from impaired conversion of carotene to vitamin A, and from fixation of vitamin A by areas of damaged liver parenchyma. Vitamin D absorption is also defective because of biliary deficiency.

To prevent these deficiencies and for possible protection against loss of glycogen from the liver, supplementary doses of these vitamins should be given to the patient. Dried yeast in divided doses, amounting to 30 to 50 gm. per day, or liquid concentrates of yeast are to be used when tolerated, especially in cases of cirrhosis. Citrus fruit juices, 250 to 360 cc. daily, should be used as a source of vitamin C. Vitamins A and D in doses of 5,000 and 1,000 I. U., respectively, given once or twice daily, are of definite value. The vitamin B furnished by the dried yeast may be supplemented parenterally with thiamine hydrochloride doses of 10 to 20 mg. and nicotinamide in doses of 50 to 100 mg., especially in cases of severe liver damage, when the patient should also receive liver extract orally, 30 cc. three times daily, or 3 to 5 cc. of crude extract parenterally, two or three times per week.

Associated with the decreased flow of bile into the intestine in jaundice is a deficient absorption of vitamin K; when the liver is damaged, there is also a decreased production of prothrombin independent of the absorption of vitamin K. Hypoprothrombinemia results from inadequate absorption or use of vitamin K and is responsible for much of the hemorrhagic tendency that is common in patients with liver disease. Capillary damage and formation of abnormal blood clots are also important factors in this hemorrhagic tendency; however, and it should be recognized that hemorrhage is not always associated with hypoprothrombinemia. Aggeler and Lucia,[19] nevertheless, suggested that it is advisable to administer vitamin K to all patients with liver disease or jaundice, regardless of the prothrombin or bleeding time. It is most important to prepare such patients well for operations; a dose of 10 mg. of vitamin K given parenterally on at least four days before operation and four days after operation is suggested as a good routine practice. Usually a dose of 5 to 10 mg. of vitamin K given parenterally or 5 to 10 mg. orally will bring the prothrombin time to a maximum in 24 hours, and the effect will persist for four days. When liver damage is so severe that there is little response to vitamin K therapy, an infusion of 500 cc. of undiluted plasma will usually correct the hypoprothrombinemia to well beyond the danger point (60% of normal).

Evidence by Meyer and Howard [20] showed that the oral administration of acetylsalicylate and sodium salicylate to human beings in daily doses of 20 to 80 grains (1.2 to 5.3 gm.) consistently produced hypoprothrombinemia and hypocoagulability of the blood. This may be prevented by administration of vitamin K with the salicylate. Hemorrhagic manifestations with acute rheumatic fever may, in some cases, be due to the administration of large doses of salicylates.

Similarly, Shapiro and associates [21] reported that in man, as in the rat, salicylate in adequate doses induces prothrombinopenia, which can be prevented by administration of vitamin K if liver function is adequate. Cirrhosis of the liver and preexisting hypoprothrombinemia augment the effect of salicylate. Acetylsalicylate appears to be more potent than sodium salicylate. The salicylates act, apparently, in the same way as bishydroxycoumarin (dicumarol®) but less effectively.

On the basis of this evidence, one might sound a note of warning as to the indiscriminate use of salicylates in diseases of the liver, particularly those associated with jaundice.

The subject of the so-called lipotropic agents, particularly choline and methionine, is still controversial. Perhaps at least part of the controversy surrounding the use of choline and its allies might be solved, as Best [22] has suggested, if lesions due to choline deficiency were distinguished from those due to other aspects of deranged liver function. If one agrees that the fatty liver is the primary evidence of choline deficiency, it should respond to appropriate therapy. So far as fatty changes occur in cirrhosis of the liver, particularly in the early stages of the process, the experimental evidence of Best and the suggestive clinical results of Morrison,[23] Steigmann,[24] Beams,[25] Beams and Endicott,[26] and Russakoff and Blumberg [27] gave support to the effectiveness of choline and methionine. In spite of the results reported by Stevens and associates,[28] it remains a crucial question whether these agents are more effective than a diet of high protein and vitamin content. One well-controlled study [29] imputed to choline and methionine a definite protein anabolic effect beyond that produced by diets adequate in protein and vitamins in patients with chronic liver damage. The authors specifically pointed to an action of choline and methionine besides the lipotropic action. Fat accumulations were not present in biopsy specimens. Other authors have denied any protein anabolic action of choline and methionine. In a recent study of some interest Cornatzer and Cayer [30] advocated that patients be selected for choline therapy on the basis of an increase of phospholipid synthesis in response to a single large (10 gm.) dose of choline. Their conclusion was based on the finding (with radioactive phosphorus techniques) that in normal patients such medication does not alter phospholipid synthesis, while in cirrhotic subjects a significant increase can be demonstrated. In summary, choline and methionine seem to be of value when fatty infiltration exists as shown by biopsy or by clinical hepatic enlargement. These agents are of possible value in chronic liver disease because of a protein anabolic effect. However, this action is controversial, and even a lipotropic action beyond that found in a high protein diet has yet to be demonstrated beyond doubt. The best indication for the use of choline is a doubt as to the adequacy of protein intake in the presence of a fatty liver. Harmful effects of both cystine and methionine given in large doses have been reported,[29] and caution in their use is therefore advisable.

CIRRHOSIS ASSOCIATED WITH OTHER DISEASE

Fatty metamorphosis of the liver, associated with diabetes mellitus, has been treated with lipocaic. Evidence supporting this treatment is to be found in the observation of Fisher [31] and Allan and co-workers [32] that depancreatized dogs treated with sufficient insulin to control the diabetic symptoms show signs of hepatic insufficiency, become insulin sensitive and die in a state of hypoglycemia within one to eight months. Postmortem studies revealed a marked fatty infiltration and degeneration of the liver as the principal or sole abnormality. By the addition of raw pancreas to the diet, Allan and his co-workers were able to prevent such hepatic changes and to permit survival for a long time. Dragstedt, Van Prohaska, and Harms [33] prepared a fat-free alcoholic extract of beef pancreas (lipocaic) that, when fed to depancreatized dogs, proved as effective as raw pancreas, lecithin, or choline. They expressed the belief that it is a "fat-metabolizing hormone" concerned in the normal transport and utilization of fat. Dragstedt [34] administered lipocaic to patients manifesting diabetes mellitus in association with heptomegaly and noted a decrease in the size of the liver. Similar observations were made by Grayzel and Radwin [35] in three cases of juvenile diabetes mellitus treated with a pancreatic extract prepared according to the method of Dragstedt and his associates. Snell and Comfort [36] also reported a rapid decrease in the size of the liver and an improvement in the hepatic function during the first 12 days of lipocaic therapy. Rosenberg [37] observed recovery after treatment with lipocaic of a patient with fatty metamorphosis of the liver associated with diabetes mellitus. Biopsies were made before and after treatment, and results were correlated with those of liver function and dextrose tolerance tests, cholesterol determinations, and clinical course. The changes observed represented the clinical counterpart of the findings noted in experimental animals.

Crude aqueous liver extract, in addition to its lipotropic activity, seems to aid in detoxication and is definitely a part of the therapeutic regimen in cases of severe liver diseases. Its activity depends partially on its content of xanthine and partially on other, unknown, factors.

Another method of administering liver extract is the intravenous use of the water-soluble preparation. This has been advocated [13] for anorexic patients, in whom it has been claimed that it enhances the appetite and thus improves caloric intake. Ralli and associates [38] have reported a prominent increase in the five year survival rate of a group of patients treated by intravenous administration of 45 to 120 cc. of liver extract weekly, compared with a control group treated by diet, vitamin supplements, and liver extract intramuscularly.

Choline therapy in doses of 3 to 4 gm. per day may be of value when evidence of fatty infiltration can be demonstrated by biopsy of the liver or is seen clinically as enlargement of the liver.

An important symptom in liver disease that requires special attention is anemia, due in part to failure of absorption of iron because of the formation of iron soaps. Administration of iron salts, therefore, may not be successful in correcting hypochromic anemia caused by liver disease until the normal bile flow is restored. The macrocytic anemia seen with the severer liver damage is treated parenterally with liver extract but does not respond as well to this therapy as does pernicious anemia until the process causing the liver damage becomes quiescent.

Calcium deficiency is another defect in mineral metabolism associated with liver disease. This deficiency is caused by the lack of bile, resulting in impaired absorption of calcium and of vitamin D, and possibly by an excessive requirement for calcium when hepatotoxins are present. Calcium diminishes the hepatotoxic action of carbon tetrachloride and of certain other toxins. However, the experimental evidence for calcium therapy is controversial; that it can do no harm is evident; one may use it because occasionally a patient may be benefited.

For some time we have advocated the use of potassium iodide in cases of jaundice, because it seemed that the bilirubinemia disappears more rapidly after the use of this salt in doses of 10 to 20 grains (0.65 to 1.3 gm.) three times a day. If there is a syphilitic factor, the indication for the use of iodides is definite. The availability of penicillin for the treatment of visceral syphilis would naturally obviate treatment with arsenical or other heavy metal preparations in the presence of liver disease.

CORTICOTROPIN AND CORTISONE THERAPY

As in virtually all diseases in which definitive therapy is lacking, the effects of corticotropin (ACTH) therapy and cortisone therapy on cirrhosis of the liver have been explored. Aterman [39] has reported that hepatic fibrosis produced in experimental animals by administration of carbon tetrachloride has been inhibited by cortisone simultaneously administered. A preliminary report of the use of cortisone in one case of biliary cirrhosis and one of serum hepatitis revealed no significant effect.[40] In a series of seven patients treated with corticotropin in daily doses of 50 to 100 mg. 6 to 28 days, no definite improvement was noted. There was suggestive improvement in albumin synthesis and a fall of bilirubin level in four young women with cirrhosis of unknown origin. Patients with Laennec's cirrhosis showed no improvement.[41] Serious complications occurred during corticotropin therapy. In three patients portal thrombosis developed, and in one a fatal esophageal hemorrhage occurred.[42] On the basis of this preliminary work, the use of corticotropin seems to be contraindicated in cases of advanced liver cirrhosis.

RETENTION OF FLUID AND SALT

The crucial factors leading to retention of fluid with ascites and edema in hepatic cirrhosis are not known. However, it seems that among the interrelated factors are portal hypertension, increased sodium retention, decreased colloid osmotic pressure of the blood, and a possible increase in antidiuretic substance. Certainly reasonable doubt has been cast on the Starling principle that the volume of the extracellular extravascular fluid is dependent entirely on a balance between capillary hydrostatic filtration pressure and the colloid osmotic pressure of the blood.[43]

Although this factor plays a role, other factors also are involved. In patients with cirrhosis of the liver, accumulation of fluid and diuresis have occurred without alteration of the total protein and albumin levels.[44] Proof is lacking that albumin influences any aspect of cirrhosis other than fluid balance. Salt-poor human albumin has received extensive clinical trial for control of ascites and edema over the past few years.[45] Janeway and his associates [46] were the first to administer salt-poor albumin intravenously in the treatment of cirrhosis. Sufficient experience has accumulated in the literature to permit certain inferences at this time as to what may be expected from intravenous administration of salt-poor human albumin. The response in apparently similar cases is variable. In most series immediate and effective diuresis with loss of ascites and edema occurred in some cases. In others, response was slow over a period of weeks or months. In still others there was no benefit whatever. One group of workers [47] showed by electrophoretic studies a pronounced and immediate rise in albumin levels and a fall in globulin. After cessation of therapy this improvement gradually declined. In some reported instances,[48] elevations in serum albumin persisted for as long as three months after treatment. Maintenance doses of 20 to 100 gm. of salt-poor human albumin per week have been advocated.[43] The usual therapeutic dose has been 100 cc. of a 25% solution given intravenously in about 45 minutes one or two times a day. The duration of therapy depends on the response.

There is evidence [45] that a considerable part of administered serum albumin enters the ascitic fluid, establishing an equilibrium between the vascular and ascitic compartments at a higher albumin level. Albumin has been found more effective when the disease is not so advanced as to require paracentesis. However, when ascitic fluid exists in large amounts, it is economical of administered albumin to employ paracentesis prior to giving the intravenous medication. It is advisable also to restrict salt intake moderately to decrease the rate of ascites formation and thereby further conserve the serum albumin.[48] Salt-poor albumin has been most effective in treatment of the nutritional type of cirrhosis.[49] There are certain serious complications of intravenous albumin therapy (Post,[45] Watson and Greenberg,[50] Havens and Bluemle,[51] and Faloon and associates [49]). These include febrile reactions, hemorrhage from esophageal varices, epistaxis, formation of pleural effusion, and acute pulmonary edema. All these complications have been frequent enough to command caution, particularly in patients with known heart disease who have had previous episodes of hematemesis. Intravenous use of salt-poor human albumin is no substitute for nutritional and other recognized therapeutic measures for cirrhosis of the liver. However, when judiciously used in conjunction with other treatment, it may prove to be a valuable adjuvant in the therapy of decompensated hepatic cirrhosis with ascites and edema. In selected instances it may be of crucial benefit in enabling a patient to survive a critical period. Patients with cirrhosis of the liver and ascites with normal salt intake excrete minimal amounts of sodium in the urine in the order of 1 mEq. per day (Faloon and associates,[52] Farnsworth,[53] and Goodyer and co-workers [54]). Such patients may have decreased sodium content in the sweat and saliva also, indicating a possible adrenal mechanism in the sodium retention of cirrhosis with ascites (Bongiovanni and Eisenmenger [42] and Eisenmenger and associates [55]). Salt loads given to cirrhotic persons with a normal glomerular filtration rate and renal blood flow revealed impairment of excretion, suggesting a possible defect in the renal tubular mechanism.[54] However, the actual mechanism of the salt retention in cases of cirrhosis is not known at this time.

In view of the marked salt retention accompanying cirrhosis with ascites and edema, salt restriction techniques have been widely used in recent years. Salt deprivation has been attempted by dietary deletion and the use of sodium ion exchange resins. Layne and Schemm,[56] Kark and associates,[57] Lowe and Overy,[58] and Eisenmenger and associates [59] have claimed diuresis and a decrease in the rate of ascites formation as a result of diets low in sodium.

Such diets must be individualized for each patient. Kark and associates [60] recommended beginning with an intake of 25 mEq. of sodium per day and reducing or increasing this amount according to the response. A sodium intake that leads to diuresis in one patient may be ineffective in another.

Patients on prolonged salt restriction diets must be watched carefully for signs of the so-called low salt syndrome (Schroeder,[61] and Janeway and associates [46]). This is manifested clinically by weakness, lassitude, muscle cramps, nausea, and a drop in pulse pressure. If it is allowed to progress, the urea nitrogen level of the serum rises, and renal failure and death may occur. Serum electrolyte studies should be used to warn of a fall in the serum sodium level and changes in the carbon-dioxide-combining power. The danger of this syndrome is particularly marked in patients with renal disease.[57] However, it may occur in cirrhotic patients with normal renal function.

Paracentesis entails less risk and may be resorted to frequently without greatly interfering with the general condition of the patient. Care must be taken not to withdraw too much fluid at one time or to withdraw it too quickly. Further, peritoneal shock should be prevented by carefully anesthetizing the peritoneum. Hypodermic solutions of atropine and epinephrine should be close at hand in case the patient suffers from the effects of peritoneal shock.

In patients whose salt intake has been restricted, abdominal paracentesis increases the danger of the salt depletion syndrome, presumably owing to the large loss of sodium in the ascitic contents. This sequence has been reported in two cases recently.[62] When a salt depletion syndrome occurs, the most effective treatment in our experience has been the intravenous administration of 5% solution of sodium chloride in an amount calculated to replace the specific sodium deficit in the extracellular compartment. This amount can be easily determined from the body weight and the serum sodium level.

In the enthusiasm for sodium restriction it is important not to compromise the therapeutic, caloric, and protein contents of the diet. Although this is difficult to guard against even when low sodium, high protein foods are used, diets maintaining proper balance can be prepared.[48] To further this end and to achieve a more palatable type of effective low sodium diet, ion exchange resins have been introduced in the treatment of cirrhosis (Goodyer and associates,[54] and McChesney and co-workers [63]). Dock has emphasized the value of cation exchange resins in the control of edematous states. Erwin and associates,[64] Martz and co-workers,[65] and Hay and Wood [66] have found that effective diuresis occurred and subsequent fluid retention was retarded in cirrhotic patients by the use of cation exchange resins. They recommended 45 to 60 gm. of resin daily in doses of 15 gm., so that the diet can contain 1 to 3 gm. of sodium per day. The resin used should be potassium, saturated so that there is no potassium deprivation, which can be a serious complication of cation exchange therapy. Ammonium chloride should not be given when an ammonium cation exchange resin is used, since this would increase the tendency to acidosis.[66] There are, however, limitations to the clinical utility of cation exchange resins, as has been recently stressed by Greenman and co-workers.[67] The in vivo efficiency of these resins is usually 1 mEq. of sodium per gram of resin. Since ordinary diets provide 100 to 300 mEq. of sodium daily, these agents, in the amounts recommended, 60 gm. per day, are obviously insufficient. Furthermore, when the dietary sodium is withheld, the efficiency of the resins decreases markedly. Both hydrogen and ammonium resins produce acidosis in addition to the deviation of sodium to stools, which can be considered a beneficial effect except in subjects with impaired renal function. Resins must be used cautiously in the presence of renal disease. As with any form of salt restriction, the danger of a low salt syndrome is present. The use of cation exchange resins has a limited place in certain instances of hepatic cirrhosis as an alternative to other methods of salt deprivation.

Mercurial diuretics may be used in treatment of liver disease. However, their effectiveness in severe chronic disease tends to be decreased after repeated use. This fact calls into play the other means of diuresis discussed earlier. When mercurial preparations are used in conjunction with salt depletion techniques, manifestations of the salt depletion syndrome must be watched for.

PORTAL HYPERTENSION

In addition to the many problems in the edema and ascites of liver disease just described, there is the mechanical problem of intrahepatic vascular obstruction and consequent portal hypertension. The problem of portal hypertension was classically delineated by Whipple [68] in 1945 and has recently been reviewed in an excellent article by Welch.[69] In 1945 Blakemore and Lord [70] outlined a feasible procedure for surgical treatment of portal hypertension. Since that time Rousselot,[71] Blakemore,[72] Linton,[73] and Gerbode and Holman [74] described the results following direct portacaval and splenorenal anastomosis. Results are better in patients with extrahepatic portal obstructions and in young persons whose liver damage is slight. In instances of cirrhosis, Blakemore [75] has stated that, while no one test of liver function is a valid criterion for the determination of a reasonable operative risk, the operation is hazardous when the serum albumin level is below 3 gm. per 100 cc. or when the sulfobromophthalein retention exceeds 35%. While cirrhosis may be the commonest cause of portal hypertension, there is no necessary correlation between the severity of the cirrhosis and the degree of portal hypertension or its manifestations. Hepatocellular dysfunction may be relatively slight in the face of prominent portal hypertension with its sequelae, hypersplenism, and hemorrhage from engorged esophageal veins. It is important to realize that these two complications of portal hypertension are the chief aspects in which improvement can be expected from operative intervention. Ascites is likely to be decreased, while liver function will not be improved. Sufficient time has not yet elapsed for definitive evaluation of the results of the operation. However, the portal decompressing procedures appear to be helpful in carefully selected cases in which manifestations of portal hypertension are marked in proportion to hepatocellular damage.

PHYSICAL ACTIVITY

Bed rest for patients with active liver disease is a cardinal therapeutic principle. It has recently received certain experimental support. Studies by Bradley [76] and Meyers [77] by venous catheterization and sulfobromophthalein clearance techniques have shown that the hepatic blood flow in cirrhotic patients is decreased or normal. Flow is decreased by standing [76] or by passive tilting of the patient to the upright position.[78] This work may offer theoretical confirmation of the clinical impression that early mobilization of patients convalescing from liver disease is detrimental. It is known that liver cells are particularly sensitive to oxygen deprivation. Decreased partial pressure of oxygen, as in high altitudes or in the presence of anemia, may cause fatty changes.[22a] Meyers [77] has shown that in the enlarged liver the hepatic arteriovenous oxygen difference varies inversely with the flow under fasting and resting conditions to give normal splanchnic oxygen consumption. Sometimes, when the liver is small and cirrhotic, the oxygen difference is not great enough to compensate for the markedly decreased hepatic blood flow, and oxygen consumption, therefore, is below normal.[77] It may be inferred that activity would further embarrass such a patient by further reducing the already impaired hepatic blood flow. One might speculate as to the value of increasing the hemoglobin level or perhaps administering oxygen to such a patient.

DIETARY REGULATION

Dietary regulation is an essential part of the treatment of liver disease. An early return of normal eating habits is one of the most important factors in the improvement of liver function after the liver has been damaged. The food should be palatable and served in an appetizing fashion, and feedings should be given at frequent intervals. Nothing is so depressing to the patient as an ill-arranged tray. He has little desire for food, and one should use every psychological effort to encourage an added caloric intake. Ravdin and his associates [79] stated that a caloric intake in excess of basal requirements is most important in protecting the liver and aiding repair of liver damage. A high caloric, highly nutritious diet is the most important single aspect of the long-term management of chronic liver disease. Such a diet should contain at least 3,500 calories. The following diet is suggested:

Foods Allowed

Cereals:	One serving daily of any type cooked or prepared cereal, i. e., enriched cream of wheat,® farina,® oatmeal, and cornflakes. Avoid those containing large amounts of bran.
Bread:	Enriched white, cracked or honey wheat, whole wheat, or rye bread, melba toast, holland rusk, zweibach, or white crackers.
Cereal substitutes:	Rice, noodles, vermicelli, spaghetti, hominy, and macaroni; all to be plainly prepared without the addition of highly seasoned or rich sauces.
Soups:	Lean broths and vegetable milk soups.
Meat:	Two servings daily of very lean meat, i. e., lamb, veal, beef, liver, chicken, or turkey; to be broiled, boiled or roasted without additional fat. Remove all visible fat. No gravies or sauces, pork, or pork products, including bacon. Four-ounce cooked portion equals *minimum serving*; may use more.
Fish:	Lean fresh water fish, i. e., perch, pike, trout, bass, or whitefish; to be broiled, boiled, poached, or baked without additional fat. None to be fried.
Cheese:	Cottage, cream, mild American or Wisconsin brick cheese. No other kinds are to be used.
Eggs:	One or two eggs daily; may be either soft boiled, poached, shirred, or scrambled over water. None to be fried.
Vegetables:	At least three or four servings daily of any type cooked or raw vegetable with the exception of raw onions, radishes, cucumbers, or sauerkraut; all to be prepared without additional fat.
Potatoes:	Mashed, baked, or boiled potatoes. None to be fried.
Fruits:	At least three or four servings daily of any type canned, stewed, or fresh fruits. One fruit should be citrus, i. e., orange or grapefruit or the juice of either.
Desserts:	Fruit as above. Simple puddings, custard, jello,® simple cakes, and wafers.
Beverages:	Three or four glasses of milk daily; may use more. Coffee in moderation, tea, decaffeinized or cereal beverages (sanka,® kaffee hag,® postum®), fruit juices, and water.
Butter:	Three teaspoons or pats per day.
Condiments:	None to be used except salt.
Sweets:	Sugar, jelly, honey, and hard candies as desired.

Foods to Avoid

Fried foods, oils, salad dressings, nuts, and peanut butter; smoked, spiced, or tinned meats or fish; pork and pork products; gravies and sauces; pies, pastries, and chocolate; alcoholic and carbonated beverages; spices and condiments.

Avoid Tobacco

*Sample Menu for Hepatic Regimen**

Breakfast	
Fruit (any type)	1 serving or more
Cereal (any type except bran)	1 serving (½ cup)
Milk	1 glass, 6 oz.
Eggs (prepared any way except fried)	1 or 2
Toast	1 slice or more
Butter	1 teaspoon or pat
Jelly	1 tablespoon
Coffee	
Cream and sugar	
10 a. m.	
High Protein Beverage†	⅓ part of recipe
Luncheon	
Meat, fish, poultry, cheese or eggs	At least a 4-oz. cooked portion of meat, fish, or poultry, or 2 eggs, or large serving of cottage, cream, or American cheese.
Vegetable	1 serving (½ cup)
Salad, vegetable—no dressing	1 average salad
Bread	1 slice or more
Butter	1 teaspoon or pat
Jelly	1 tablespoon
Fruit (any type)	1 serving or more
Milk	1 glass, 6 oz.
3 p. m.	
High Protein Beverage	⅓ part of recipe
Dinner	
Meat, fish or poultry	At least a 4-oz. cooked portion
Potatoes (any way except fried)	1 average serving or more
Vegetable	1 serving (½ cup)
Salad, fruit or vegetable—no dressing	1 average salad
Bread	1 slice or more
Butter	1 teaspoon or pat
Jelly	1 tablespoon
Fruit (any type)	1 serving or more
Milk	1 glass, 6 oz.
Bedtime	
High Protein Beverage	⅓ part of recipe
Crackers	2 double or more

*Hepatic diet with starlac® feeding has the following approximate content: protein, 170; fat, 172; and carbohydrate, 357 (total calories, 3,656). Hepatic diet with protenum® feeding has the following approximate content: protein, 170; fat, 173; and carbohydrate, 353 (total calories, 3,649). Hepatic diet with protelac® feeding has the following approximate content: protein, 168; fat, 172; and carbohydrate, 329 (total calories, 3,536).

†High protein beverage: starlac® (product of the Borden Company), 6 tablespoons; milk, 1½ cups; cream (coffee), 1½ cups; sugar, 7 teaspoons; eggs, 3; and vanilla, 3 teaspoons. Beat eggs, sugar, vanilla, milk, and cream until well blended. Sprinkle starlac® over mixture. Beat until well mixed.

Recent studies by Chalmers and Davidson,[14] Jones and Volweiler,[80] and Patek [81] indicate that an optimal distribution of the caloric content includes protein elements to the amount of 1.5 to 2 gm. per kilogram of body weight per day. This gives some margin of safety over the amount usually allowed, which has been shown to support liver repair (Kimball and Chapple [82] and Kark and associates [57]). Protein is the most effective dietary agent in protecting the liver from damage and in promoting its repair.[81] Indeed, it has been argued [83] that, when dietary protein intake is adequate, little will be gained by supplemental amino acid or lipotropic therapy. This assertion will be alluded to later.

The carbohydrate fraction of the diet should also be as high as possible to supply the bulk of the caloric needs and to exert a protein-sparing influence.

The indictment of fat in the diet of patients with liver disease is not well supported in recent clinical literature (Chalmers and Davidson,[14] Jones and Volwiler,[80] and Patek [81]). While it is true that liver damage in the experimental animal has been produced by diets high in fat,[15] these diets were also deficient in protein elements. When protein intake is adequate, it is questionable whether a diet high in fat leads to liver damage.[84] Convincing clinical studies have shown that a diet of 3,500 calories that provides adequate protein may contain up to 175 gm. of fat and still be effective in the management of decompensated liver cirrhosis. The pertinent point is that fat should not be restricted below the level needed to allow a palatable diet and thus the desired high caloric intake. In general, fats of vegetable or dairy origin are better tolerated than those from meat sources.

HEPATIC FAILURE, COMA, AND JAUNDICE

The patient with severe liver disease is in danger of hepatic failure and coma. Here intensive intravenous use of dextrose, salt-poor human albumin, protein hydrolysates, liver extract, blood transfusions, and plasma in judicious combinations may be lifesaving. Oxygen therapy is necessary with these measures, to combat the hepatotoxic effects of anoxemia. Oxygen is best given in an oxygen tent. The use of nasal catheters is contraindicated, because pressure necrosis from the rubber may result from a possible uremic state, which can form a part of the clinical picture. We have seen severe pharyngitis and erosions of the nose with subsequent bleeding follow the use of rubber tubes in the nose and mouth.

Of the complications that occur in cases of jaundice, acute hepatic insufficiency and hemorrhage are the most important. Jaundice in patients with cirrhosis of the liver may appear as a transitory, almost unnoticed, episode; yet it should be considered a serious sign. Bed rest is imperative and hospitalization is required in cirrhotic patients with jaundice.[65] Finally, the whole therapeutic approach to this problem should be controlled by repeated laboratory investigations, which would indicate the improvement, if any, that has taken place in the liver as the result of the treatment outlined. We cannot urge too strongly the need for a conservative and scientific approach to the treatment of jaundice. One should not be too eager to operate just because of the presence of bilirubinemia, and one should not delay operation in a patient with a definite surgical type of jaundice. There is no substitute for keen clinical judgment with respect to this disease.

After the jaundice has disappeared and definite clinical improvement has been noted in patients disabled by liver disease, ambulatory management should be continued for many months, until results of repeated liver function tests indicate restoration to normal. When this has been brought about, the patient should be warned against exposing himself to the factors that brought about the original condition. In spite of the recent emphasis on dietary deficiency in the genesis of cirrhosis,[9] there is no change in the traditional interdiction of the use of alcohol in the management of the disease.

SUMMARY

The incidence of cirrhosis is increasing. The use of sulfonamides and other hepatotoxic agents and the occurrence of serum homologous hepatitis and epidemic hepatitis of World War II may be partly responsible. Recognition of the cause of liver disease is necessary for effective therapy.

Patients should be at bed rest and preferably hospitalized. The decrease in hepatic blood flow of cirrhotic patients while standing offers theoretical confirmation of the clinical impression that early mobilization of these patients is detrimental. Bed rest is imperative during jaundice in cirrhotic patients. A high caloric, high protein diet is important in the long-term management of chronic liver disease. A diet of 3,500 calories is suggested.

Intravenous infusion of carbohydrates is desirable, in order to hasten the regeneration of liver parenchyma. In patients with atrophic cirrhosis and ascites, the use of hypertonic dextrose solution induces diuresis. Infusions of amino acids may be necessary in order to maintain normal nitrogen balance in patients unable to eat a full diet. Administration of whole blood or plasma may be beneficial when there is marked hypoproteinemia, anemia, or a hemorrhagic tendency.

While it has become almost routine to include supplementary administration of vitamin B complex to cirrhotic patients, definite evidence of deficiency in cirrhotics, per se, has not been demonstrated. Vitamin K should be administered regardless of prothrombin or bleeding time. Vitamin A and D in doses of 25,000 to 50,000 units, given one or two times daily, are of definite value. Choline and methionine seem to be of value when fatty infiltration of the liver exists, although this is controversial, and their action other than that found in a high protein diet has yet to be demonstrated beyond doubt. The use of crude aqueous liver extract seems to aid in detoxication and should be a part of the therapeutic regimen for patients with severe liver disease. Intravenous use of a water-soluble liver extract has been recommended for anorexic patients. We advocate use of potassium iodide in cases of jaundice. If syphilis is a causative factor, the indication for the iodide is definite.

Although the crucial factors leading to retention of fluid with ascites and edema in cirrhotic patients are not known, the employment of salt restriction and diuretics as well as salt-poor albumin is suggested; however, such use is not without certain dangers.

The value of the administration of cation exchange resins is limited, since the amount recommended, 60 gm. per day, is insufficient and larger doses are impractical. Patients on prolonged salt restriction must be watched carefully for signs of the low salt syndrome. Abdominal paracentesis increases this danger when preceded by severe salt restriction and the use of diuretics. On the basis of preliminary work, corticotropin (ACTH) therapy and cortisone therapy seem to be contraindicated in treatment of severe liver cirrhosis. Surgical treatment of portal hypertension has its best indications in patients with extrahepatic portal obstruction and is hazardous when there is a marked liver insufficiency.

Although the laboratory studies have become very important tools for the diagnosis and management of liver disease, they are more valuable when interpreted in the light of keen clinical observation.

104 S. Michigan Ave.

Workmen's Compensation Laws.—The first real contribution to industrial diseases of the skin was made by Ramazzini in the year 1700. His unexcelled description of the dermatoses of bakers, farmers, silk-workers, washer-women and others has won him the appellation of "father of industrial hygiene."

Appreciation of the importance of industrial diseases has been recent in this country, and compensation laws were not enacted until well into the 20th century. The Federal Government made the first provision for compensation of injured employees in 1908. In 1911 the state of Wisconsin established the first Workmen's Compensation Law. Since then all states have enacted legislation to deal with industrial injuries. Frank C. Combes, M.D., Dermatology Problems in Establishment of Workmen's Compensation Claims, *Compensation Medicine,* March-May, 1952.

TECHNIQUES AND INTERPRETATION OF ROUTINE BLOOD CULTURES

OBSERVATIONS IN FIVE THOUSAND CONSECUTIVE PATIENTS

Paul Kotin, M.D., Los Angeles

Blood cultures are often essential in the diagnosis and prognosis of disease. Frequently, however, the results obtained are difficult to interpret and correlate with the clinical state of the patient. Limitations and confusions resulting may be attributable to (1) contamination due to faulty technique in the drawing of blood or in laboratory procedures, (2) preconceived ideas of bacterial "nonpathogenicity," and (3) variations in techniques of blood culture.

Bacteria can be recovered from the blood stream during physiological states and under all pathological conditions from minimal local infections to septicemias. The significance of an organism recovered from the blood stream lies in its meeting certain basic criteria. This study was made in an attempt to correlate the clinical status and the laboratory findings in patients who have had blood drawn for cultures. Certain criteria to facilitate this correlation were established.

Arnold[1] experimentally produced frank bacteremia in dogs by introducing a highly acid chyme into the small intestine from the stomach. This resulted in increased permeability of the wall of the small intestine to bacteria. Arnold further demonstrated that certain physiological alterations in the body, such as adaptations to extremes of temperature, whether artificially induced or from disease, may result in bacteremia. Cirrincione and Francona,[2] also working on dogs, were able to confirm Arnold's findings.

Reith and Squier[3] reported a study of 293 subjects, of whom 278 were male, who had blood drawn for culture at random intervals while they were performing their usual daily occupations. All were subjected to a thorough physical examination, including dental x-rays. Bacterial growth resulted in 113 of the 293 cases. In 48 the bacteria were considered frank contaminants, while in 65 they were considered as being in the blood at the time of culture. An increase in positive blood cultures was noted during the months when upper respiratory tract infections were common, suggesting that they may, in part, be responsible for the rise.

Kulka[4] obtained positive blood cultures from apparently healthy women during menstruation, and Kobak,[5] using umbilical vessel blood cultures, confirmed the physiological entry of bacteria into the blood stream. The presence of bacteria in the blood during apparent health has resulted in studies on possible foci and primary sites from which the organisms invade the blood. Horder[6] as early as 1908 observed the "undoubted fact that the infective agent in most cases of subacute bacterial endocarditis was derived from the mouth." Libman[7] in 1918 reported that alpha streptococci were "constantly invading the blood from foci in the upper respiratory tract and oral cavities, even during periods of inactivity of the foci." Lewis and Grant[8] concluded that invasion of the blood stream is a common event in patients with diseased heart valves. They further state that such invasions are encountered in the great majority of cases without mishap and that an "almost physiological entry" of organisms into the blood stream of the average person constantly occurs. King,[9] in observations on 2,233 consecutive blood cultures, felt that "casual bacteremias" occurred rarely but, nevertheless, did occur.

Minimal trauma as a cause of bacteremia was demonstrated by Murray and Moosnick,[10] who obtained positive blood cultures from patients with chronic dental disease after they had chewed paraffin for one-half hour. Round and Kirkpatrick,[11] Burket and Burn,[12] and Okell and Elliott[13] all demonstrated bacteremia following intraoral manipulations. Hirsh[14] and his associates, using control studies, demonstrated the prophylactic value of penicillin in controlling such bacteremias. McEntegart and Porterfield[15] concluded that bacteremia following oral manipulations was related to the degree of trauma rather than to the intensity of oral sepsis.

Trauma, in the form of operative procedures on or about foci of infection, has repeatedly been observed to be followed by bacteremia. Seifert[16] reported that, 10 minutes after drainage of a variety of abscesses, positive blood cultures with organisms identical to those in the

abscesses were obtained in 45% of his cases. Richards[17] demonstrated bacteremia following vigorous massage of foci of infection in 15% of 376 cases. Bacteremia, as one of the factors in radiation sickness, has been described by Warren[18] and Lawrence and Tennant.[19] Miller[20] and his associates have experimentally corroborated this observation.

Laboratory technique for blood cultures was different in every report reviewed. Extremes vary from single inoculation of one laboratory medium to fractionation of blood samples with inoculation of multiple mediums under both aerobic and anaerobic conditions. Skin preparation varied from simple alcohol swabbing to surgical preparation of the skin.

Variations in techniques, as well as differences in evaluation and clinical correlation of results of blood cultures, made an analysis of common factors in all references cited difficult. These differences, associated with the failure on the part of many workers to recognize the presence of bacteremia during various physiological conditions, emphasized the need for uniform methods of technique and interpretation of blood cultures.

Organisms recovered from blood cultures were used as the foundation for determining the correlation of bacteremia and the clinical state of the patient in this study. Bacteria whose pathogenic status is controversial, e. g., coagulase-negative Staphylococcus albus, diphtheroids, and Bacteroides, were given special study. The criteria established for interrelation of blood cultures reported here include (1) a consistent technique of sample drawing, (2) uniform methods of bacterial identification, (3) repeated cultures in series, and (4) compensation for complicating effects of chemotherapy and antibiotic therapy.

METHOD AND MATERIAL

Blood cultures of 5,000 consecutive patients, made at the Los Angeles County Hospital, Acute Unit, from Jan. 1, 1949, to Jan. 13, 1950, were reviewed. All blood cultures were routine. Clinical charts of all patients having positive blood cultures were reviewed, and bacteriologic-clinical relationships were analyzed and reviewed.

Five to 10 cc. of blood was obtained from the cubital vein through alcohol-prepared skin. The blood was inoculated into 6-oz. (170-gm.) medicine bottles through rubber-lined screw caps with central perforations. Mediums consisted of 100 cc. of DIFCO tryptose and phosphate broth with dextrose. A like amount of bile broth with dextrose was used for Salmonella, and 20 cc. of tryptose citrate broth was used for Brucella. To all mediums 1% paraaminobenzoic acid was added at the time of preparation as advised by Woods.[21] Penicillinase was added to the culture mediums from patients being treated with penicillin. All specimens were incubated at 37 C. Routine cultures were inspected daily the first week and semiweekly the second week. In the absence of growth, cultures were discarded at the end of the second week. Cultures for Brucella were placed in a 10% carbon dioxide environment after 48 hours. Every four to five days cultures were examined by smear. Subcultures were made the same time to tryptose agar slants, which were also incubated under carbon dioxide conditions. In the absence of growth in four weeks they were discarded as negative.

RESULTS

Bacterial growth resulted in 665, or 13%, of the 5,000 cases reviewed. Approximately half (325) the organisms recovered in this study demonstrated bacteriologic-clinical correlation. Multiple invasion of the blood was demonstrated in 45 patients. Specific pathogenicity of the remaining half (340) was either indefinite or not thoroughly established.

On the basis of their probable etiological correlation with the diagnosis of the patient, organisms were placed into one of two groups, designated A and B. Bacteria were placed in group A if (1) an accepted etiological relationship between organism and disease existed, as in the case of meningococcemia and pneumococcemia, (2) repeated blood cultures grew organisms in which clinical correlation was probable, (3) disappearance of the organism from the blood paralleled clinical recovery, (4) bacteria recovered from the blood were identical with those recovered from foci of infection, and (5) in case of death, postmortem blood cultures corroborated the antemortem cultures. They were placed in group B if (1) organisms were obtained in only one of repeated blood cultures and in addition a specific etiological relationship was lacking, (2) the organisms, though potentially pathogenic, were not definitely related to the current illness of the patient, and (3) the organisms are accepted as being ubiquitous, e. g., Bacillus subtilis.

The accompanying table lists organisms on the basis of their grouping and their relationships to the clinical states of the patients. Organisms listed as belonging to group A with established pathogenicity need not be discussed in detail, as they fulfil the criteria for inclusion in group A. Organisms showing questionable pathogenicity are responsible for existing confusion and their status is in need of clarification.

COMMENT

The results of blood culture may be definitive in establishing a clinical diagnosis and determining the prognosis in any given case. Past clinical confusion in interpretaton has been dependent on the following factors: (1) unawareness of bacteremic states during apparent health and in association with minimal trauma, (2) preconceived ideas of certain "nonpathogenic" attributes of certain organisms, (3) disregard of special considerations of pediatric bacteriology, (4) lack of correlation with associated diseases in the host, (5) lack of standard technique of blood culture, and (6) failure to compensate for antibiotic and chemotherapeutic agents.

Bacterial invasion of the blood during health, during physiological alterations in the body, and during disease has been amply observed clinically and corroborated experimentally. Organisms recovered from the blood during health and after minimal trauma as reviewed in the introduction were considered to be chiefly and usually "nonpathogenic." The ability of these bacteria to multiply in the blood stream is usually low, and their power to produce a septicemic state is limited. Their presence is transient. These "nonpathogens," however, constitute a distinct threat to patients with chronic disease such as valvular heart disease. Loewe [22] and his associates, MacNeal and Blevins,[23] and McMillan [24] have demonstrated the role of oral alpha streptococci in the production of bacterial endocarditis.

Pediatric bacteriology as applied to blood culture requires special consideration. Organisms effectively overcome by adults can be both morbid and fatal to infants in spite of treatment. All the cases of Staph. albus, coagulase-negative, in group A were in cultures from pediatric patients. Gram-negative bacilli also demonstrated an increased pathogenicity in infants and children having limited immune mechanisms. An excellent opportunity for comparing antemortem and postmortem blood cultures was made possible by the high percentage of autopsies on the pediatric service. Blood culture results could be correlated in 20 of 27 cases. Of these, coliform bacilli were present alone or as part of a multiple invasion in 16 cases in sufficient numbers to indicate blood stream invasion in life. In instances of multiple invasion, so-called nonpathogens have been associated with disease production. Kanof and Kramer [25] reported 24 cases of multiple invasion in children; organisms usually considered spurious invaders were associated etiologically with the death of two.

The role of metabolic diseases and other associated disturbances in physiological processes affect the role of the host in resistance to bacteremia. A high incidence of diabetes and azotemia was observed among patients in whom facultative pathogens produced disease. Any alterations in immune response due to these factors require consideration.

Review of the literature showed a lack of comparable blood culture techniques. No correlation between the more elaborate methods of skin preparation and a decrease in contamination could be established. The time of obtaining the blood specimens for culture bore little relation to the incidence of positive cultures. The frequency in terms of times per day of obtaining blood for culture revealed no percentage difference of positive recovery attributable to the time factor. Multiple or complex mediums showed no increase in positive blood cultures.

Recent therapeutic advances have introduced new complications into blood culture studies. The use of para-aminobenzoic acid and penicillinase when indicated is fundamental.

An analysis of the diseases associated with blood stream invasion in this study emphasizes the importance of the above considerations. Except for B. subtilis, no organism can be considered as an invariable contaminant. Clostridium welchii and Bacteroides, though placed in group B exclusively, have been shown by numerous other studies to be capable of producing septicemia. Nine organisms are listed in group A-B. The so-called nonpathogens, such as Staph. albus and diphtheroids, fulfil the criteria set up for pathogenicity and in certain cases were considered of etiological significance. All organisms exclusive of B. subtilis placed in group B were not considered as contaminants, but rather their presence was accepted as being part of the large group of blood stream invaders during periods of physiological alteration, whatever the cause. Organisms in group B most frequently were associated with an initial positive blood culture followed by repeated negative ones. The failure to grow the organisms repeatedly may be explained by the institution of treatment immediately after the initial blood culture. Low virulence associated with their rapid destruction, along with the possibility of few circulating organisms, also may have contributed to their absence from subsequent blood cultures. Bacteriologic-clinical correlation was uniformly absent in cases in which group B organisms were grown.

SUMMARY

A review of blood cultures of 5,000 consecutive patients indicated the need for and resulted in the establishment of certain criteria for blood culture study, bacteriologic interpretation, and clinical correlation. These criteria included factors affecting the organism, the host, and therapeutic regimens.

Blood for culture was obtained through alcohol-prepared skin with no special considerations as to time of day or number of samples per day. Bacterial growth resulted in 665, or 13%, of the 5,000 cases reviewed. In 50% of the cases the organisms were classified in group A, indicating positive bacterial-clinical correlation in that they fulfilled the following criteria: (1) an accepted etiological relationship between organism and disease existed, as in the case of meningococcemia and pneumococcemia; (2) repeated blood cultures resulted in growth in which clinical correlation was probable; (3) disappearance of the organism from the blood paralleled clinical recovery; (4) bacteria recovered from the blood were identical with those recovered from foci of infection; and (5) in case of death, postmortem blood culture resulted in bacterial growth identical to that obtained in antemortem cultures. In the remaining 50% of the cases the organisms were classified in group B and were considered as "nonpathogenic" invaders because they (1) were obtained in only one of repeated blood cultures during the same disease and a specific etiological relationship was lacking; (2) though potentially pathogenic, were clinically unrelated to the current illness of the patient; and (3) are accepted as being invariable external contaminants, such as Bacillus subtilis.

The following organisms fitted into both groups in accordance with their roles in individual specific clinical states and as such may be classified as having pathogenic capabilities: alpha Streptococcus viridans, indifferent Streptococcus, indifferent micro-aerophilic Streptococcus, coagulase-negative Staphylococcus albus, Escherichia coli, Aerobacter aerogenes, Proteus vulgaris, Proteus morganii, Alkaligenes fecalis, Pseudomonas aeruginosa, nonspecific Eberthella, and diphtheroids. The recovery of organisms from blood culture in cases in which clinical-bacteriologic correlation is absent does not necessarily indicate laboratory contamination, but rather the possibility of bacteremia in association with physiological states or periods of physiological alteration, following both minimal and severe trauma, as well as during septicemic diseases.

FACTORS INFLUENCING RUPTURE OF THE HEART AFTER MYOCARDIAL INFARCTION

Robert W. Oblath, M.D., David C. Levinson, M.D.
and
George C. Griffith, M.D., Los Angeles

It is the purpose of this paper to review the factors related to the occurrence of rupture or perforation of the heart after myocardial infarction. Rupture of the heart has been recognized for over 300 years, and in recent times it has been the subject of thorough autopsy and clinical evaluation. The following salient facts have become established through previous investigations: 1. Such ruptures rarely occur in patients younger than 50 years of age.[1] 2. Patients who have unlimited activity after infarction occurs apparently have a higher incidence of rupture than those treated with "adequate" rest.[2] 3. Rupture associated with infarction almost universally occurs in the first few weeks following infarction; it rarely if ever occurs in an old scar.[3] 4. The chances of rupture occurring are three times greater in patients in whom hypertension persists after infarction than in those who have normal or subnormal blood pressures.[1a] 5. Myocardial necrosis is apparently a necessary prior condition for the occurrence of rupture.[4]

In an effort to find further information, we reviewed the records of 80 patients who died at the Los Angeles County Hospital between July, 1941, and October, 1951, of perforation of the heart with hemopericardium and cardiac tamponade. During this time there were, in addition, 11 patients who died from the effects of rupture of the interventricular septum following recent myocardial infarction. (Detailed analyses of the records of these 11 patients have not been included in this report.) Completed autopsy statistics are available at this hospital for the period July 1, 1941, to December 31, 1948, inclusive. In that period there were 13,665 autopsies; of these, 1,026 (7.58%) were performed on patients who died after recent myocardial infarction. Of this latter

---

Read before the Clinical Session of the American Medical Association, Los Angeles, Dec. 5, 1951.

Autopsy records were made available by Dr. E. M. Butt of the Department of Pathology, Los Angeles County Hospital.

From the Department of Medicine (Cardiology), School of Medicine, University of Southern California and the Los Angeles County Hospital.

group, 73 patients, 7.11% of those with recent infarction and 0.53% of all patients on whom autopsies were done, died of cardiac rupture, either perforation through a free wall of the heart or perforation through the interventricular septum.

RESULTS OF REVIEW

The clinical, electrocardiographic (when available), and pathological records of these 80 patients were reviewed.

Clinical Records.—In both men and women the greatest incidence of rupture occurred in the seventh and eighth decades of life (table 1). None of the patients was less than 50 years of age. The average age of the men was 69.75 years and of the women, 72 years. The sex difference observed was striking: 33 patients (41.25%) were male and 47 (58.75%) were female. Regarding race, 79 were Caucasian and 1 was Negro.

Because of past emphasis on the fact that physical activity in the postinfarction period may be related to the incidence of rupture and because of recent articles relative to early activity in patients with infarction, the time of onset of infarction was carefully estimated from the history obtained in each case. The length of time from the estimated onset to entry into the hospital and the length of life from the time of estimated onset to rupture were calculated as carefully as possible.

The length of time from estimated clinical onset to entry into the hospital was as follows: 16 (20%) patients were in the hospital and in bed within 6 hours; another 9 (11.25%) entered between 7 and 12 hours after onset; 13 (16.25%) entered between 13 and 24 hours after onset. In addition, 11 patients (13.75%) were in the hospital at bed rest at the time of onset of the infarction. The remainder entered from 1 to 21 days after onset, 9 entering on the second day and 6 on the third day. Sixty-four patients (80%), therefore, either were already in the hospital at onset of infarction or entered within 72 hours afterward. Of the group entering later than that, several had been under the care of physicians at home or in private hospitals. Sex differences were apparent in this analysis: 17 men (51.5%) were admitted within 24 hours after onset of infarction, but only 20 women (42.7%) entered during the same period.

The length of life from estimated clinical onset to time of rupture was as follows: 14 (17.5%) patients died in less than 24 hours; 10 (12.5%) died on the second day; and 12 (15%) died on the third day; thus, a total of 36 (45%) patients died within the first 3 days of infarction. Another 27 (33.75%) died between the 4th and 12th days. In 11 instances, length of life after infarction was unknown, and in 6 instances, death occurred from 19 to 30 days after onset of infarction. Sex differences were found here also: 19 men (57.6%) and only 17 women (36.2%) died within the first 3 days.

Blood pressure observations, where available, were similar to those reported in the past.[1a] In cases in which preinfarction pressures were known, they were with few exceptions abnormally high. Following infarction, the pressure dropped to normal levels in a few cases, but the majority reflected either persistent hypertension or a drop to shock pressures.

The relation of digitalis therapy, causing increased myocardial contractility, to rupture of the heart has in the past been the subject of speculation.[1d] Ten (12.5%) of the patients reviewed had been receiving maintenance doses of digitalis, and 4 others were given digitalis in the last 2 to 4 days of life because of evidence of congestive failure. Thus, there is no concrete evidence to be derived from this series that suggests a significant relationship between digitalis administration and myocardial rupture. Similarly, quinidine sulfate, which was administered terminally to only 3 patients, cannot be implicated.

Electrocardiographic Records.—Electrocardiograms made in the recent antemortem period were available for 42 of the patients and for another 5 who died in the two year period 1939 to 1941. Electrocardiograms of 26 patients were made within 24 hours of death, those of 12 within 48 hours, of 4 within 72 hours, and of 5 within 96 hours. Records of four patients were made by the standard limb and multiple unipolar lead technique; records of three others were made by the standard limb leads plus multiple CF leads, and records of the remainder were made by the standard limb leads and lead CF_4.

TABLE 1.—*Distribution of Patients by Age, Sex, and Race*

Sex	Age, Yr.				Total	Average Age	Race	
	50-59	60-69	70-79	80-89			Caucasian	Negro
Men............	4	11	15	3	33	69.75	33	0
Women........	3	16	18	10	47	72	46	1

Nothing was found in tracings made by the standard and unipolar limb leads that could be correlated in any way with the later development of cardiac rupture. At best, these leads indicated only myocardial infarction. Chest lead tracings showed the following characteristics in patients with anterior wall and posterior wall perforation: 1. Anterior wall perforation—two patients in this group had multiple unipolar precordial leads, and in each, two or more positions showed QS waves characteristic of full-thickness myocardial infarction (fig. 1). In 2 subjects with multiple CF leads, QS waves appeared in two or more leads. A single lead, CF_4, was made in 30 patients; 20 of these had only QS complexes, 6 had deep Q waves, and 4 had essentially normal waves.

2. *Posterior wall perforation*—2 patients had unipolar precordial leads; in one there was a QS complex in lead V_6 (fig. 2), and in the other all precordial leads were normal. One patient had multiple CF leads, and a deep Q wave was found in leads CF_5 and CF_6. Of 10 patients examined with lead CF_4 only, 1 had a deep Q wave and the other 9 had normal QRS complexes.

Pathological Records.—The problem of pathological changes in the heart occurring after myocardial rupture has been extensively studied by competent pathologists.[5] In brief, the predominant changes apparently are extensive necrosis, undermining, and dissection of the myocardium. We have found no need to review the detailed histopathological condition of the hearts studied in our group, but we have attempted only to define the location of the infarct (table 2) and the location of the rupture (table 3) and then to determine if there is a predilection for any specific part of the heart to rupture.

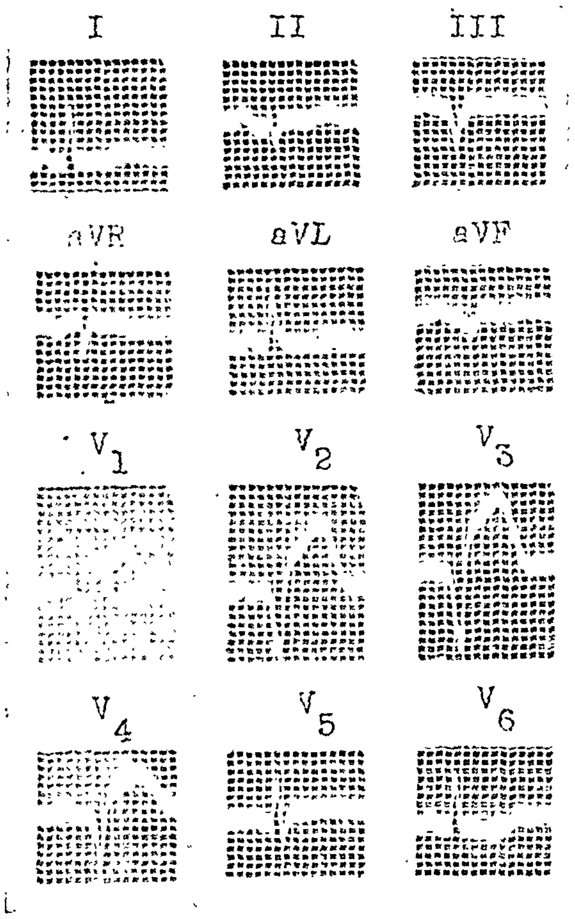

Fig. 1.—Electrocardiogram of patient with anterior myocardial rupture. Note the evidence of full-thickness infarction (QS waves) in leads V_1 through V_4.

In 77 (96.25%) patients, the infarcts were of the left ventricle, and in 3 they were of the right ventricle alone. In 11 (14.3%) of the 77 with infarction of the left ventricle, the infarction had spread to a portion of the right ventricle; in 46 (59.6%) the infarction was anterior, in 28 (36.4%) it was posterior, and in 3 (4%) it was lateral. Detailed subdivision of the locations of infarctions appears in table 2, but it may be noted that of the patients with anterior infarctions, the *septum* was involved in 31 (67.4%), and of those with posterior infarctions, the septum was involved in 17 (60.7%); of the entire group, therefore, the *septum* was involved in 50 patients (62.5%).

The distribution of the locations of ruptures is shown in table 3. Anterior left ventricle perforation occurred in 37 (46.25%) of the patients; in 31 (86.5%) of these, it was parallel to, in, or immediately adjacent to the interventricular septum. Posterior left ventricle perforation occurred in 25 (31.25%); in 16 (64%) of these, it was parallel to, in, or adjacent to the interventricular septum. In 9 the rupture was in the lateral left ventricle. In 7 it was through the right ventricle and was related to the interventricular septum. Multiple anterior perforations occurred in two instances, with specific locations of each perforation not given.

It is apparent, then, that in 54 (67.5%) of the entire group the rupture was parallel to, in, or immediately adjacent to the interventricular septum. It is also apparent that although the septum was actually involved in only 67.4% of those with anterior infarctions, in 86.5% of those with anterior ruptures the ruptures were *intimately* related to that structure.

TABLE 2.—*Location of Infarctions*

Location	No. of Patients	
Left ventricle (total)		77
Anterior (total)		46
Entire anterior wall	5	
Anterior wall and intraventricular septum	31	
Anterior wall and septum	14	
Anterior-apical and septum	12	
Anterior, septum, and right ventricle	4	
Anterior wall and basal septum	1	
Anterior-basal	1	
Anterior-lateral	6	
Anterior-apical	1	
Anterior-apical and lateral	1	
Posterior (total)		28
Entire posterior wall	3	
Posterior wall and intraventricular septum	17	
Posterior-basal and septum	2	
Midposterior wall and septum	2	
Posterior, septum, and right ventricle	7	
Posterior wall and septum, entire length of septum	4	
Posterior-lateral and septum	2	
Posterior-basal and posterior papillary muscle	1	
Midposterior wall	2	
Posterior-apical	2	
Posterior-lateral	3	
Lateral (total)		3
Right ventricle (total)		3
Anterior-apical and intraventricular septum	2	
Apical-lateral	1	
Total		80

In this entire group, the great majority of perforations were dissections, often by devious routes, from endocardium to pericardium. The length of dissection in each instance was variable; not only did blood dissect in a tortuous course through the ventricular wall in many cases, but in several instances the path was through the ventricular wall for several centimeters and then into the septum, parallel to the two septal surfaces, with final perforation into the pericardial cavity from the septum itself. The so-called blowout occurred in only a few instances, and in each of these it was through either the free lateral wall of the left ventricle or through an extensively necrotic anterior wall of the left ventricle.

(*c*) Lodge-Patch, I.: The Ageing of Cardiac Infarcts, and Its Influence on Cardiac Rupture, Brit. Heart J. **13**: 37, 1951.

COMMENT

Comparison of our data with figures obtained at an earlier period at the Los Angeles County Hospital by Edmondson and Hoxie[1a] shows that the increase in the number of patients with myocardial infarctions, about which they commented, has continued since the time of their study. Of all patients on whom autopsies were performed during the years they reviewed, 3.4% had one or more unhealed myocardial infarctions. Over twice that number (7.58%) were found in the same classification in the present study. The number of patients with rupture of the heart, however, was similar in the two series, with 8.3% in their group and 7.11% in ours. The generally accepted incidence in the accumulated literature is about 9%.[1d]

Age, Sex, and Race.—Our figures on age, sex, and race are worthy of further comment. Not one of our group, including the unreported series of 11 patients with interventricular septal perforation, was below the age of 50 years; by far the highest incidence for both sexes occurred between ages 60 and 80 years. On its face, this data apparently is good evidence that the clinician need have little fear of cardiac rupture in patients below the age of 50 years. Regarding sex, women have an incidence of myocardial infarction in various autopsy and clinical studies only one-fourth[6] to one-seventh[7] as high as men. When considered in the light of sex differences, as revealed by an autopsy "population" study by Zinn and Cosby,[1c] the autopsy incidence is about equal for the two sexes. In our group of 80 patients with cardiac rupture, however, 47 (58.75%) were women and only 33 (41.25%) were men. This difference is certainly significant and indicates the greater danger that this complication holds for women than for men. Especially is this so if it is recalled that the peak incidence of myocardial infarction in women occurs at a later age than in men. As far as race is concerned, it has been shown in certain series that the Negro race has a lower incidence of infarction than the Caucasian in a given autopsy population. This is borne out in our series, only 1 of 80 patients being Negro.

TABLE 3.—*Location of Ruptures*

Location		No. of Patients
Anterior left ventricle (total)		37
Parallel to, in, or near intraventricular septum	31

Relation of Activity to Rupture.—Previous studies have shown that in certain instances there is a definite relation between the degree of activity after infarction and myocardial rupture. Because of the specialized classification of the patients considered in at least one such study,[1c] this problem was reevaluated. As has been noted above, 49 (61.25%) of the patients in our series were in the hospital and in bed either at the time of or within 24 hours after onset of infarction. It is difficult to conceive how the course of events in these patients could have been affected by activity. In addition, as mentioned earlier, several of the patients who entered relatively late in the postinfarction period had been in other hospitals or otherwise under the care of private physicians. If it is assumed that all or some of these patients were kept at rest before transfer to the Los Angeles County Hospital, then the available evidence suggests even more strongly that activity does not play an important role in the development of myocardial rupture. There may be exceptions in certain special instances or in cases in which activity has been actually excessive. That there may be a relation between activity and myocardial rupture, however, is possible. This is based on consideration of the fact that while 58.75% of the ruptures occurred in women, only 42.7% of the women entered the hospital during the first 24 hours. On the other hand, while only 41.25% of the perforations occurred in men, 51.5% of the men entered the hospital in the first 24 hours.

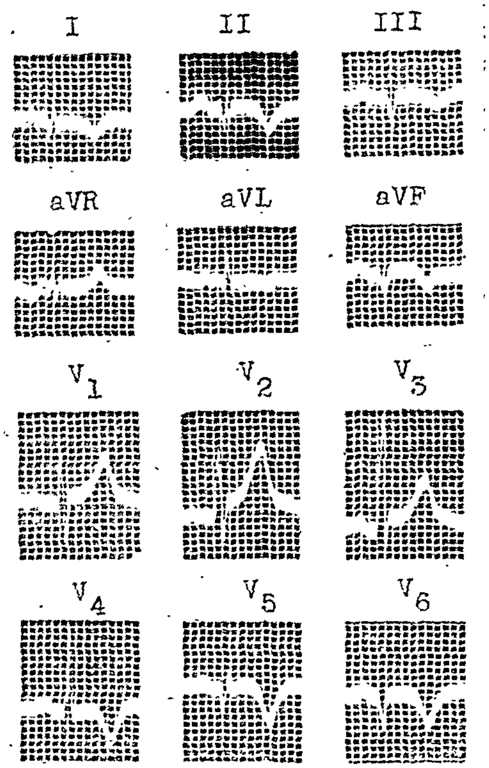

Fig. 2.—Electrocardiogram of patient with posterior myocardial rupture. Note that evidence of full-thickness infarction does not appear until lead V_6.

It has been stated repeatedly that the majority of deaths from myocardial rupture occur from the 2nd to

the 10th day after infarction. Our figures do not differ greatly from these previously reported values. It is of interest, however, that in 36 (45%) patients rupture occurred within the first 72 hours; in 14 of these, in fact, it occurred within the first 24 hours, and in 10 within the second 24 hours. In one instance, a patient previously well reported for work, suddenly collapsed, and died. Several others were brought to the admitting room of the hospital because of severe chest pain and died at most only a few hours after onset of pain, before more than a cursory examination could be performed. On the other hand, rupture occurred after 19 days in 6 patients. At autopsy these patients had only the infarcts that had caused hospitalization; no evidence of more recent infarction was found. The maximum time after infarction of which we could be reasonably certain was 30 days. It is probably of significance that while approximately equal numbers of men and women died within the first 3 days (19 and 17, respectively), the percentage distribution was 57.6% men and 36.2% women. Men apparently are in greater jeopardy during the immediate postinfarction period.

Electrocardiographic Observations.—Myocardial necrosis is considered essential for development of the rupture, according to pathologists. If presently accepted electrocardiographic concepts are valid, semidirect leads over these areas should record only QS waves. The evidence obtained in this study appears to agree with that concept. In multiple precordial leads made in cases of anterior infarctions, a full-thickness infarct pattern (QS) was obtained at one or more areas. In cases in which a single lead, CF_4, was made, QS complexes were recorded in a majority of instances. In six patients with deep Q waves, lateral or medial displacement of the electrode theoretically would have revealed QS complexes. The ease with which the anterior and lateral portions of the heart may be explored electrocardiographically should enable the clinician to determine with a high degree of accuracy the extent of an infarction in those locations, both in thickness and in surface area involved. In our series, infarctions and ruptures were in anterior or lateral portions of the heart in 66.6% of the patients. In a recent survey of the literature [1d] it was shown that ruptures were anterior in 75% of 80 patients in whom the position of the rupture was reported. It would appear evident, then, that a clue to the possibility of impending rupture (i. e., a full-thickness infarct) may be elicited in two-thirds to three-fourths of the patients who will suffer this catastrophe.

The situation is somewhat different in the case of posterior rupture. Some evidence was obtained from lateral chest leads, but not with the same degree of certainty as in the case of anterior rupture. Esophageal or back leads would be of aid—the former if it were feasible to use these leads in critically ill patients, and the latter if they were in more general use and the criteria of normalcy were more definitely known.

Location of Infarcts and Ruptures.—It is well recognized that the majority of myocardial infarctions occur in the left ventricle. Wartman and Hellerstein [8] reviewed 235 infarcts in 160 patients. They found that the anterior half of the interventricular septum was involved in 54% of the patients who had an infarct of the anterior portion of the left ventricle. The posterior half of the septum was involved in 25% of posterior infarctions. Our series gives a somewhat distorted picture because of the fact that we considered only recent infarctions, although relatively few of the patients had old scars. Nevertheless, as noted earlier, 67.4% of anterior infarctions and 60.7% of posterior infarctions involved the septum. All infarctions in the right or left ventricle that involved the septum constituted 62.5% of the total. While percentage values based on such dissimilar series are difficult to compare, the extreme differences between them show that there tends to be a greater incidence of infarcts involving the septum in myocardial rupture than in those instances in which there is healing or death due to other causes.

Although loosely considered statistics may be fallacious, it is interesting to note that in 54 (67.5%) patients the perforations were intimately related to the septum. There appears to be a definite relationship between the number infarcts involving the septum and the affinity of perforations for the septum. Also, while the infarcts were confined solely to the right ventricle in only three patients, ruptures occurred in the right ventricle in seven. Finally, it is important to realize that few of the "ruptures" were actually ruptures in the sense of an area of heart muscle suddenly blown out of place. Almost all were dissections and perforations. This is generally true, also, of cases reported in the literature. No explanation is immediately apparent for this high percentage of infarcts and perforations that are intimately related to the interventricular septum. No explanation will be attempted here beyond consideration of a few possibilities. First, with the septum relatively fixed between the two ventricles, contraction may result in a tear along a line of "cleavage" between contracting myocardium and nonfunctioning necrotic tissues. Second, the initial tear through which blood later dissects may be related to the various muscle bundles of the heart and the ways in which they may work against or with each other during contraction.

Experimental work reported several years ago showed that intraventricular pressure apparently was not related to the development of rupture.[9] The large number of dissections, the small number of blowouts, and the fact that in 4 patients with both right and left ventricular infarctions the rupture occurred in the relatively low pressure right ventricle all suggest that only infrequently does intraventricular pressure alone play a significant role. Beyond some specific facts gleaned from a survey of autopsies, there is little we can state as to exactly why a given heart will rupture.

SUMMARY

1. Eighty patients who died in the period 1941 to 1951 of perforation of the myocardium with hemopericardium and cardiac tamponade have been reviewed. All of the

---

[8] Wartman, W. B., and Hellerstein, H. K.: The Incidence of Heart Disease in 2,000 Consecutive Autopsies, Ann. Int. Med. 28:41, 1948.

[9] Thomas, W. C.: Clinicopathologic and Experimental Observations on the Pathogenesis of Rupture of the Heart Due to Myocardial Damage, Am. J. Path. 23:904, 1947.

patients were over the age of 50 years. Women predominated over men (47 and 33, respectively). Only one of the group was Negro; the remainder were Caucasian.

2. Sixty-four (80%) of the patients were either in the hospital in bed or entered the hospital within the first 72 hours after infarction occurred. A higher percentage of men died within the first 72 hours than women (57.6% of the men and 36.2% of the women). Of all patients, 36 (45%) died within the first 72 hours of infarction.

3. Contrary to previous speculation, there was no evidence that digitalis administration was related to myocardial rupture.

4. Multiple unipolar lead electrocardiograms may give evidence of impending rupture by showing a full-thickness infarct pattern in anterior infarction in patients who otherwise fit the general clinical picture of those reviewed here.

5. The interventricular septum was involved in infarction in a greater number of these patients than could probably be expected in a random sampling of recent infarcts found at autopsy. Of the entire group, 67.5% had ruptures parallel to, in, or immediately adjacent to the interventricular septum.

6. The great majority of ruptures were dissections and perforations; only a few were "blowouts."

7. In general, with the exception that the amount of postinfarction activity these patients underwent did not appear significant, the results of the clinical survey did not differ considerably from the results of previous investigations referred to in the introduction.

SPEECH REHABILITATION AFTER TOTAL REMOVAL OF LARYNX

Nathaniel M. Levin, M.D., Miami, Fla.

The problems that confront the patient who has undergone a radical laryngeal resection are generally not too well known. To present a total picture of the person who has undergone radical laryngectomy and his problems is one of the aims of this paper. Further, it is our purpose to show that practically all patients, after a total laryngectomy, can acquire a natural form of speech [1] without the use of any artificial aid and that they can resume their former occupations and activities requiring the use of the voice.

The number of patients with cancer of the larynx who have a total laryngectomy is increasing yearly.[2] They number in the thousands. Physicians in many communities in the United States and other countries now have to care for many more of these persons, whose medical needs are many, sometimes unique. The necessity for speech rehabilitation after the operation is now more widely recognized. Formerly it was believed that it was essential only to operate and save a life. Now it is realized that the laryngeal amputation is just the beginning and that the restoration of practical speech to the patient must follow.

After a radical laryngectomy the patient's entire economic and social status abruptly changes. Emotionally, a terrific blow has been sustained. He has been given a diagnosis of cancer; a serious operation and hospitalization follow; and immediately after the operation the patient is entirely speechless. The economic and other handicaps that will follow must be considered, for a radical readjustment of the patient's entire life is necessary. Only those dealing with large numbers of such patients can fill in the unhappy details.[3] Needless to say, the patient's discharge does not constitute the end of the case; it is just the beginning of the rehabilitation program that must follow.

The severest handicap that remains after the operation is the absence of speech. It is regrettable that patients are sometimes discharged without being informed that esophageal speech is a definite possibility. It is important that they be told this before the operation is started in order to prepare them emotionally for the postoperative and convalescent period. Patients are often discharged simply with a sheet of instructions on the use of the artificial voice box. Formerly, patients were dismissed without instructions of any kind in relation to speech therapy; however, this omission is fortunately becoming rarer. Surgeons who remove the larynx now assume the additional obligation of initiating a training program for their patients. The artificial mechanical devices should be reserved for the exceptional patient who cannot master esophageal speech for some special reason.[1] The mechanical larynx, aside from its other deficiencies, produces a tone that does not remotely resemble the human voice.

ALTERED ANATOMY AND PHYSIOLOGY AFTER THE OPERATION

Since esophageal speech depends on the remaining and altered anatomy and physiology, the more important changes following total laryngectomy will now be reviewed. After surgery the patient no longer inhales or exhales air through the nose and mouth. Only the esophagus connects with the mouth and nasopharynx, for the airway has been disconnected. A new orifice has been created in the neck where the tracheal stump has been sutured to the skin. Through this opening air is piped down into the lungs, and this air is sometimes exhaled with a noticeable hissing sound. The patient is now

affect future esophageal speech requirements. Further experience in this regard is needed.[5]

The mortality and morbidity rates incidental to a laryngectomy have been reduced to minimal figures. With the help of the antibiotics, sulfonamides, whole blood transfusions, good anesthesia, and nutritional intravenous therapy, the period of hospitalization has been markedly reduced, from 8 to 12 weeks to 10 to 18 days. The total laryngectomy is recommended as the procedure of choice in selected cases of carcinoma of the larynx.[6] Additional radical neck dissection may be required in some cases. Five-year cures occur in 60% of the total number of patients operated on, many of whom live out their normal life spans. By contrast, deep x-ray therapy promises five-year cures in only 10% of patients.[6] Following radiation, there is, of course, no loss of speech.[7] The ideal procedure is the partial laryngectomy (laryngofissure), for it results in five-year cures in 75 to 85% of patients, without any serious impairment of speech.[8] Unfortunately, not too many qualify, for usually when the patient appears for biopsy, the growth has already extended beyond the scope of this operation.

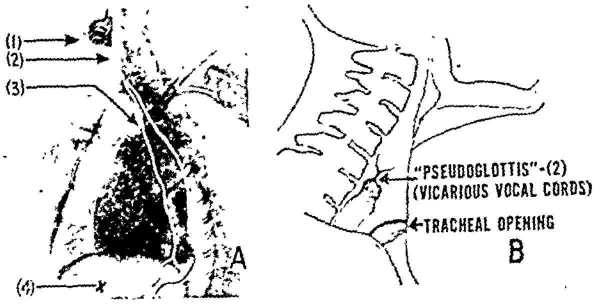

Fig. 3.—*A*, roentgenographic demonstration of esophageal speech mechanism (patient is saying "church"): (1) air-distended pharyngeal pouch; (2) vibrating upper esophageal sphincter, acting as substitute vocal cords (pseudoglottis); (3) air-distended esophagus; (4) gastric air, not ordinarily utilized in this speech mechanism. *B*, schematic representation of *A*, to show substitute vocal cords approximating at exact instant that a sound is produced.

MECHANISM OF ESOPHAGEAL SPEECH

The mechanism on which esophageal speech is based is fundamentally simple.[9] This mechanism utilizes structures that normally remain after the operation or that, if altered, can be trained to assume new functions. A comparison of the mechanisms of normal speech with those found in patients who have undergone total laryngectomy shows that the basic essentials for producing sound in both are the same. In each, a moving column of air from below vibrates closely approximated mucous membrane surfaces, thus producing a sound. The sound is then delivered into the mouth, where it is converted into words and sentences (speech) by the lips, teeth, tongue, and palate (the "molds of speech").

Esophageal speech differs from normal communication mainly in the anatomic structures involved. Normally, air from the lungs passes, on exhalation, up through the narrow aperture of the closely approximated and vibrating vocal cords (the glottis). In esophageal speech, the air pocketed in the upper esophagus passes upward through the closely approximated membranous surfaces of the vibrating cricopharyngeal sphincter (the pseudoglottis) into the hypopharynx. The sound thus produced is converted into speech by the "molds," which remain unaltered after surgery. I accomplished visualization of the substitute vocal cords in action, by radiography, in 1939.[1] It was clearly demonstrated that the folds of the cricopharyngeal sphincter approximated and vibrated at the exact moment that sound was produced and thus closely resembled the action of the true vocal cords on phonation. A column of air escaping through the vibrating sphincter constitutes the mechanism of sound production in esophageal speech. Normally this is also the mechanism that acts in belching. If this column of air can be controlled by prolonging the expulsion at will, the patient can then produce sounds that are converted into esophageal speech.[10]

It is neither a miracle nor a coincidence that air expelled from the upper alimentary tract can be used for producing sounds that can be converted into speech. In some animals and birds, sounds are normally produced by the use of anatomic structures other than the larynx. At times the upper esophageal sphincter must be removed to completely eliminate an extensive malignant lesion. In such cases other tissues may have to take over the function of substitute vocal cords in the hypopharynx. These tissues may be membranous or scar tissue folds, or combinations of these. The base of the tongue against the posterior pharyngeal wall, for example, can also be made to vibrate.

The upper alimentary tract offers a very satisfactory substitute for the respiratory tract in the new speech mechanism. The muscular cricopharyngeal sphincter is strategically situated at the mouth of the esophagus (pharyngoesophageal junction), approximately at the former level of the removed larynx. This muscular ring normally remains contracted and opens reflexly only during swallowing, vomiting, or belching. Since this sphincter also has striated fibers under voluntary control, it can be trained to act as a substitute for the vocal cords. The central nervous system still controls the speech mechanism, even though the larynx has been removed and the lungs are no longer necessary for speech production. The thorax still acts in a normal way, but on an inflated esophagus instead of on the air-filled lungs as in normal speech.[11]

The mechanism of esophageal speech in continuous action can best be described by a composite picture made up of repeated clinical observations on patients who have had total laryngectomy and by fluoroscopic and radiographic evidence.[12] The student begins to talk by closing his mouth, thus forcing air down into the pharynx, which

becomes dilated; then the cricopharyngeal sphincter suddenly opens, permitting the air to go down into the esophagus. All this occurs with amazing rapidity. Immediately after the air is aspirated or swallowed, the esophagus dilates considerably. When the patient begins to make a sound, the air is forced upward, by a rising diaphragm, through the sphincter into the pharynx. The resulting sound is immediately converted into speech. As the patient gains facility by practicing the intake and subsequent expulsion of air, the act becomes much easier and faster. Later it becomes an involuntary reflex entirely. The gastric air pocket is not utilized in the speech mechanism of trained patients, a fact that is easily demonstrated by fluoroscopy or radiography.[13]

METHODS OF INSTRUCTION AND TRAINING

Formal instruction is necessary for most laryngectomy patients to acquire esophageal speech.[14] Occasionally a patient stumbles spontaneously into an excellent method by trial and error; however, learning need not depend on chance but can be directed by using methods that are known to be effective. Before a course of training is initiated, the patient must be examined to determine whether he is a suitable candidate. In the preliminary examination it must be established by fluoroscopy and radiography whether the hypopharyngeal pocket is ample and the upper esophageal sphincter functionally normal. At the same time the status of the respiratory function and the cardiovascular system is ascertained. The nose and throat are examined, and the hypopharynx and the esophageal mouth are inspected with a laryngeal mirror or, if necessary, an endoscope. A search is made for metastases, and the general health of the patient is considered.[1] Hearing must be adequate.

Preliminary orientation and training[15] may begin before the operation, whenever possible. After the operation the patient communicates by writing and is not permitted to attempt speech until the pharynx is completely healed. Whispered speech is ineffective, and it is prohibited because it interferes with the development of esophageal speech. Under ideal conditions, and as soon as the patient's physical condition permits, systematic raining should begin. In addition to those patients who e regularly receiving speech instruction, convalescent atients and those scheduled for surgery may "sit in" during these classes. The psychological benefit for the latter is considerable.

A résumé of training methods used in successful speech rehabilitation[1] follows. 1. Patients are given an outline of the anatomic and physiological changes following the operation. They are taught that they must disassociate the separate functions of respiration through the tracheal orifice in the neck and aerophagia and phonation. Most patients grasp this idea readily. 2. Students begin to practice the aspiration and swallowing of air and its subsequent expulsion. Sipping carbonated liquids or water aids in the sensation of filling the hypopharyngeal pocket, because the effervescence helps in expelling this accumulation. 3. Using this expelled air, patients practice such easy words as church, scram, welsh, and others, and they are pleasantly surprised when these initial efforts result in clearly audible words. With the knowledge that they can now make themselves understood, there is considerable encouragement. 4. One-syllable words can readily be managed with one swallow of air; later, a sequence of syllables can be produced with an equal volume of air. 5. Combinations of various consonants with vowels are practiced, and, after the mastery of short words, words of more than one syllable are attempted. Long words are broken up into their component parts; thus, San Francisco becomes San-Fran-Cis-Co. 6. A series of short words are then combined into simple sentences, with the emphasis on clarity and sharp, clear diction. The intake of air is characterized by labored interruptions, as this is a deliberate, voluntary act. Later, the patient no longer consciously swallows or aspirates the air, as it has now become almost entirely a reflex habit.

Students are thoroughly drilled in each of the preceding steps for an hour daily. At the end of two weeks they can make nearly all of the fundamental sounds, say short words, and combine words into simple sentences. During the next three or four weeks the effort is directed toward polishing the speech and eliminating various defects, such as loud expiratory blowing sounds issuing from the tracheal orifice, gulping noises on swallowing air, unnatural lip movements, poor articulation, and others. Students can now practice three to four hours daily in interrupted periods.

Intelligence, willingness, and the determination to learn are essential requirements for the mastery of esophageal speech. Previous education is a help but not absolutely necessary. Some individual instruction is necessary, particularly in the initial and advanced periods of training. Beginners are much encouraged when they hear trained students talking. At the end of a month of instruction, the trainee usually talks quite well. His words are clear, and he is understood by almost everyone, although a few speech defects may remain. The patient is now ready for the test of talking to his friends and associates. Timid students are encouraged to listen to the new voice on a recording, so that they can appreciate the improvement and progress they have made. The hoarseness that characterizes early speech becomes less noticeable as students acquire greater facility and the voice more flexibility. Women learn to talk with the same ease as men. Persons who have undergone total laryngectomy generally present no unusual problems in training. Some however, have difficulties and peculiarities that require the experienced handling of a laryngologist who is also a teacher. The speech therapist should therefore consult with the surgeon to learn about the postoperative anatomic status of the difficult students. Some of this group have poor speech and show no progress in training, while others are using the mechanical devices unwillingly. These persons, of course, require special consideration.

Those who have accomplished esophageal speech come from all walks of life. We have trained salesmen, laborers, executives, engineers, society matrons, attorneys, housewives, a pharmacist, and others. Laryngectomy patients of all ages can be taught to master esophageal speech. The oldest student was well past 70, and the youngest was 29. It is much easier to train patients if instruction begins shortly after the operation; however, patients have mastered this method after periods of months to years. One man learned to talk after a 22-year interval. Patients using mechanical devices can learn to talk and thus discontinue these artificial aids. The patient past 60 learns without too much difficulty if he has the desire to do so. Those who have a negative attitude or are depressed are at times difficult to train. Failures have been comparatively few, for those who could not acquire the method were either in ill health, depressed, or would not apply themselves sufficiently.

---

[13] Levin.[1] Morrison.[10b] Lindsay.[12c]

[14] Levin.[1] Morrison.[10b]

[15] McCall, J. W.: Preoperative Training for Development of Esophageal Voice in Laryngectomized Patients, Ann. Otol., Rhin. & Laryng. 52:364, 1943.

The patient who has mastered esophageal speech is able to talk distinctly in a normal way. The voice is satisfactory for normal speech activities and does not attract unusual attention, though it is somewhat harsh at first. A few patients develop voices so nearly normal that they are not recognized as laryngeal amputees, and their speech improves steadily over a number of years if correct methods are used.

ARTIFICIAL LARYNX AND OTHER MECHANICAL DEVICES

There are two common mechanical speech devices in use today: 1. The reed type of artificial larynx, which pipes air from the tracheal opening into the mouth, after a sound is produced by a vibrating reed. The resulting sound is then converted into a mechanical, artificial speech by the normal speech molds. 2. The electrolarynx, which is essentially a battery driven vibrator over which a diaphragm is stretched. This device is held against the neck. As the diaphragm vibrates, sound waves produced within the pharynx are delivered into the mouth and are articulated into a mechanical and muffled speech. The buzzing sounds resemble an electric razor in action.

Many of the patients who came for speech training were using artificial aids, but none was satisfied with them, even when they could use them successfully. All the patients were anxious to discard these mechanical prostheses, giving as the main objections and reasons that (1) they were conspicuous, attracting unwelcome attention; (2) they made the resulting voice unnatural and unpleasant, with a monotonous quality not resembling the human voice; and (3) they served as a constant reminder of the disability. Some patients who came for training had never used the artificial larynx, not having tried to master the artificial speech technique. Most patients were never informed that it takes as long to master these appliances as it does to acquire the more natural esophageal speech. Once speech is acquired, the aids are dispensed with in most instances. One patient preferred to use the instrument for telephone conversation only; another, a plant foreman, found that the artificial voice box carried well over the noises of machinery. An attorney who had been using the artificial larynx for 12 years was never reconciled to its use. He mastered esophageal speech in eight weeks, though his volume is still low because of the extremely radical neck, dissection procedure required in his case.

The artificial larynx is a poor substitute for a natural voice, and these mechanical devices should be reserved for only those few persons who cannot master esophageal speech for some special reason, such as (1) stenosis of the esophagus after extensive removal of a widespread malignant lesion; (2) resection of the cervical portion of the esophagus; (3) multiple handicaps; for example, laryngectomy plus deafness; (4) suspected recurrence, metastasis, or multiple lesions; for example, a bronchial carcinoma in addition to the laryngeal lesion; and (5) senility or other feebleness.

EMOTIONAL AND PSYCHOLOGICAL CONSIDERATIONS

Emotional disturbances of varying degree occur in nearly all of the patients.[3] While the introverted person suffers more in proportion, even the extrovert is depressed when he finds himself entirely speechless. These reactions are to be expected, because (1) the patient has undergone a major operation after confirmation of a serious diagnosis; (2) on discharge from the hospital he must return to his previous environment, with all of the economic and social problems involved, and where loss of speech is a serious defect; and (3) he has a fear of the recurrence of cancer, open or hidden, but definitely present. Formerly the patient faced the prospect of total laryngectomy with gloomy foreboding, the questions uppermost always being, "Will I survive?" and "What about my speech?" A hopeful answer can be justifiably given because of the five-year (and longer) cures that are on record.[16] Since the postlaryngectomy period requires major emotional and psychological adjustments, the chronically depressed type of person is not ordinarily recommended for this radical procedure without careful consideration.

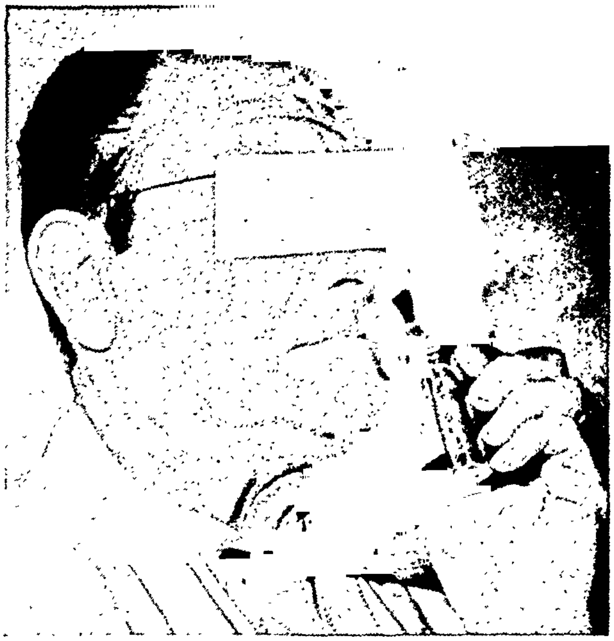

Fig. 4.—Laryngectomy patient using reed-type artificial larynx. Patients find mechanical devices such as this objectionable, because (1) they are conspicuous and attract unwelcome attention; (2) the resulting voice is mechanical and monotonous; and (3) they require the constant use of at least one hand, thus are impractical for bimanual job requirements.

REHABILITATION

Persons who have undergone total laryngectomy are located in many of the communities of the United States and other countries. Physicians who assume the care of these patients are very much interested in their unique and peculiar requirements. They must be supervised, instructed, and checked for a number of years. Certain restrictions must be observed by these patients:[16] (1) They should not engage in occupations in which they will be constantly exposed to dust or irritating fumes and sprays. (2) Obviously they must use precaution while bathing and should keep out of deep water, since this is always an additional hazard. (3) They must guard against aspirating foreign bodies or debris through the vulnerable tracheal orifice. A gauze apron worn over the opening offers considerable protection against dust and wind. (4) Patients who wear trachea tubes must have these cleansed and changed regularly, and the tracheal orifice should be watched for irritation and recurrence of malignant disease.

The rehabilitation program for these patients should start preoperatively,[15] when they are assured that they can talk again. They are much encouraged when they hear others who have mastered esophageal speech, and they should be advised to enroll for a course of speech training promptly. This is by far the most constructive part of this program and the best morale booster. Insight into the total need of these patients came only with my integrated experience acquired in the combined roles of laryngologist, laryngeal surgeon, and speech teacher. My contact with this large group since 1932 convinces me that these patients are optimistic as to their present problems and their future outlook when they have proper aid in adjustment. The majority are able to resume their former occupations or other employment requiring the use of the voice, even over the telephone. Some have addressed groups in public and over the radio. Although several patients have come from neighboring countries for speech therapy, language differences did not present any real problems. Most of these rehabilitated patients have made admirable adjustment to their former lives.

Esophageal speech training has elicited a widespread interest among physicians, medical institutions, and university speech departments. The vocational rehabilitation divisions of several of the southern states have shown an active interest in salvaging these persons. They have adopted very practical programs and have helped to return many speech handicapped persons to gainful employment. One man who came for speech training had won an election as state senator, using an artificial device during the campaign. Even though successful, he was never reconciled to the use of this aid. He learned esophageal speech in about eight weeks, then discarded the aid. Now, intensely interested in the rehabilitation of persons like himself, he has been instrumental in effecting legislation that provides for subsidizing esophageal speech training in his state.

Pioneering work has established esophageal speech on a more solid foundation. Increasing interest is attracting laryngologists and speech pathologists to do more original work in this field, although there is still need for more cooperative effort in the interest of these handicapped persons. In addition to the training facilities now available, there is need for more active teaching programs, both for patients and teachers, in well-located centers.

SUMMARY AND CONCLUSIONS

A total picture of the patient who has undergone radical laryngectomy and his problems is presented. It is shown that nearly all these patients can return to occupations and activities requiring the use of the voice. The more important characteristics of the altered anatomy and physiology following this radical procedure are reviewed. While total loss of speech is most important, there are other marked changes that require consideration. The emotional and psychological disturbances following the operation are also considered.

Esophageal speech depends on certain anatomic structures, the most important of which are the hypopharynx and the upper esophageal sphincter. Laryngeal surgeons make every effort to conserve these and other normal structures that is consistent with adequate removal of the malignant tissue. The mechanism of esophageal speech is described. There is considerable interest in those structures that anatomically and physiologically take over the functions of the resected larynx. A résumé of successful methods of instruction used in esophageal speech training is outlined. The artificial larynx and other mechanical devices are discussed.

A rehabilitation program essential for these patients is outlined. The number of such patients is increasing yearly, because surgical techniques now assure from 50 to 60% of five-year cures (and longer), and many of them attain their normal life expectancy.

Patients can now be reasonably assured of a practical speech development after total laryngeal resection. Mechanical aids, with all of their deficiencies and disadvantages, are unsatisfactory and should be reserved for those few patients who cannot learn a more natural form of speech because of special difficulties. In short, the possibility of vocal loss should no longer deter the physician from considering the total laryngectomy operation as the procedure of choice when indicated. Esophageal speech adequately compensates for the loss of this important function.

Cleft Lip.—*In newborn babies with cleft* lip alone or combined with cleft palate, the first treatment of course is concerned with surgical closure of the lip. Regarding early treatment, it should be stated that cleft lip and cleft palate do not constitute a surgical emergency. Frequently, the physician who has delivered a baby with one or both of these anomalies is under the impression that immediate closure of the cleft is imperative to enable the baby to nurse, and that without surgical closure starvation is imminent. This is erroneous. The surest way to kill a baby in a poor condition of nutrition is to operate on *it. No operation should be done until the child begins to gain weight and is otherwise in good physical condition.* By the use of a little ingenuity, feeding can be carried on by medicine dropper, spoon or special feeders. Swallowing is greatly facilitated by holding the baby during feeding in the upright position. Some surgeons, prompted possibly by the natural anxiety of the parents to have the deformity masked as soon as possible, advocate operation on the lip within a few days after birth. We do not subscribe to this, as we feel that accurate coaptation of the cleft edges is more difficult when the parts are so small and that much better end-results are obtained by waiting until the child is six weeks to three months old.—Robert H. Ivy, M.D., Modern Concept of Cleft Lip and Cleft Palate Management, *Plastic and Reconstructive Surgery*, February, 1952.

GENITOURINARY LESIONS IN LEPROSY

WITH SPECIAL REFERENCE TO THE PROBLEM OF ATROPHY OF THE TESTES

Harry Grabstald, M.D., Norfolk, Va.
and
Lawrence L. Swan, M.D., New Orleans

Genitourinary lesions specifically related to leprosy (Hansen's disease) are relatively few. Of considerable clinical interest and importance are the frequent leprous orchitis, testicular atrophy, and gynecomastia. A review of urologic literature reveals no reference to involvement of organs of the genitourinary tract by the Mycobacterium leprae. Of the standard urologic textbooks only Young's [1] refers to leprous orchitis.

In the general literature of leprosy only passing reference is made to the genitourinary manifestations. Fox and Knott [2] described cutaneous leprous nodules on the scrotum and penis in 4 of 34 male patients. Serra [3] examined 200 patients with leprosy, describing vulvar lesions in 13%, preputial lesions in 10%, and lesions of the balanic sulcus in 5%. These lesions were especially common in patients with the nodular and mixed types of leprosy, although it is known that macular leprosy of the penis and vulva often mimics primary chancre. One patient presented a nodular lesion at the balanopreputial sulcus following intercourse with a woman known to have leprosy. Inguinal lymphadenopathy developed, and Myco. leprae were found on microscopic examination.

The diagnostician must be particularly wary in many cases, for two surveys conducted by the United States Public Health Service revealed that in presumably nonsyphilitic leprous patients there were 45% to 59% false positive serologic reactions for syphilis.[4] In fact, it has been estimated that approximately half of the patients admitted to the National Leprosarium at Carville, La., have had a diagnosis of syphilis made sometime prior to admission.[5]

In Serra's group of 200 patients with leprosy, testis and epididymal involvement was described in 97% and 29%, respectively. Bacilli have been described in the epididymis and in the rete testis, and Kobayashi [6] has even described bacilli in the seminal ejaculum. In a series of 842 patients with leprosy Baptista [7] described gynecomastia in 72 (8.6%). In another group of 292, gynecomastia was observed in 17 (5.8%).

While the kidney and more rarely the adrenal are frequently involved in a nonspecific type of amyloidosis similar to that seen in other degenerative diseases, no significant renal or adrenal lesion characteristic of leprosy has been described. Nephritis has been a frequent finding. The degree of renal and adrenal amyloidosis is often pronounced, and in large areas of many kidney sections the glomeruli are almost completely obliterated by amyloid. The adrenals are less commonly infiltrated by amyloid. Ureteral, bladder, or prostatic involvement by any process peculiar to leprosy has not been recorded to the best of our knowledge.[8]

It is the problem of leprous orchitis and atrophy that forms the basis for this preliminary report, in which a few of the clinical findings are correlated with the histological changes observed in the testis.

MATERIAL AND METHODS

One hundred seventy-nine male patients of the United States Public Health Service Hospital, Carville, La., were examined. In 154, only the breasts and testes were observed. In 25, more detailed examinations were carried out, including high-span and caliper testis measurements. In addition, notation was made concerning beard growth, voice changes, thyroid cartilage size, ejaculation, impotence, temporal recession of hair, trunk and axillary hair, pubic hair, and external genitalia. When it became apparent that height-span measurements were not indicative of an eunuchoidal skeletal structure, sole to symphysis pubis and symphysis pubis to vertex measurements were not made.

Formal biopsy specimens of the testis were obtained from three patients, two of whom had gynecomastia. Breast material was available from one of those who had previously undergone mammoplasty. Sections of breast were typical of classical gynecomastia, so that further studies with relation to the gynecomastia were not emphasized.

In addition to biopsy sections of the testis, tissue obtained post mortem from 17 patients with lepromatous leprosy was fixed in formaldehyde (formalin®) for study. Microscopic sections of the testes were stained with hematoxylin and eosin and for acid-fast organisms. Selected sections of testes were stained with Masson's trichrome and congo red. Urinary 17-ketosteroids and gonadotropins were determined in two patients subjected to testis biopsy.[9]

PATHOLOGICAL CHANGES

In every patient examined there was definite microscopic evidence of severe involvement of the testis. The histological changes varied markedly; these changes have been arbitrarily divided into three phases: (1) vascular, (2) interstitial, and (3) obliterative.

Read before the U. S. Public Health Service Clinical Society, Detroit, June 7, 1952.

Vascular Phase (Active Leprous Orchitis).—The major changes during this phase are vascular. The vessels of all sizes are infiltrated by lymphocytes. The width of the vessel wall is increased at the expense of the lumen (fig. 1), and lepromas are occasionally seen as nodules projecting into the lumen. Perivascularly, in the interstitial tissues, there are numerous lymphocytes, large pale cells, and vacuoles measuring up to 40 μ. Acid-fast organisms are present in impressive numbers (fig. 2). Many of the vacuoles seen with the hematoxylin and eosin stain are globi containing packets of Myco. leprae, and the large pale cells have many bacteria contained within their cytoplasm. These are the lepra, or Virchow, cells. Acid-fast bacilli are also present in the vessel walls and globi, and lepra cells are observed in the interluminal lepromas. There are all phases of spermatogenesis during this stage. The Sertoli cells and the interstitial cells of Leydig are not affected. The basement membrane and lamina propria of the tubules are not changed.

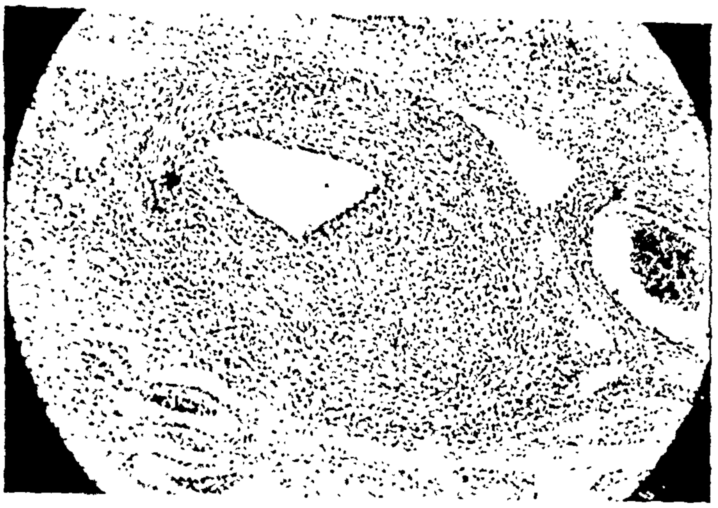

Fig. 1.—Lymphocytic infiltration of artery immediately adjacent to the tunica albuginia. There is widening of the arteriole wall and perivascular lymphocytic infiltration (hematoxylin and eosin × 83).

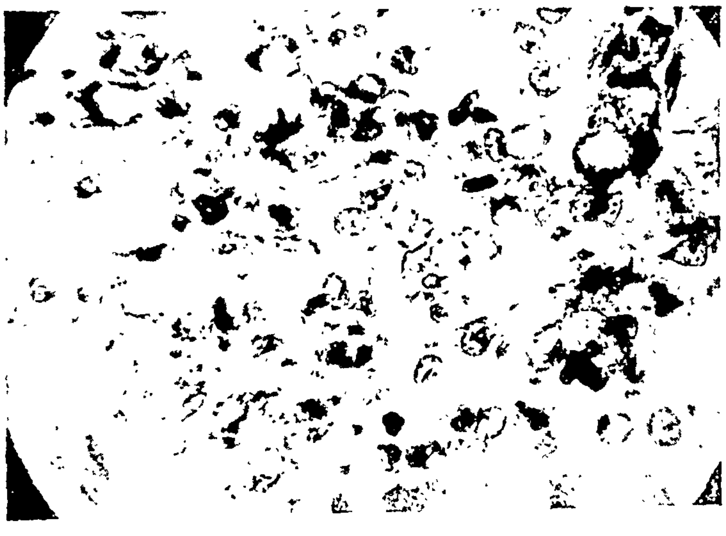

Fig. 2.—Acute leprous orchitis; acid-fast preparation showing typical organisms (× 430).

Interstitial Cell Phase.—Gradations into this phase are gradual, showing progressive reactive obliterative endarteritis, but the major findings consist of masses of Leydig cell clumps and interstitial fibrosis (fig. 3). The vessel walls are moderately to greatly thickened but lack any evidence of active inflammation as described in the preceding phase. The interstitial tissues show diffuse collagen deposition, with aggregates of Leydig cells. These cells appear to be larger, more eosinophilic, and granular than normal. There are numerous coarse brown granules in the cytoplasm in the so-called ectoplasmic zones of many cells. Crystalloid forms have not been observed within the cytoplasm. The seminiferous tubules are seen to be relatively smaller. The lumens are almost entirely filled with Sertolian syncytium. Occasionally spermatogonia are seen, but no mature spermatozoa are found. The basement membrane is wider than normal, and the lamina propria is considerably widened by concentric lamellae of delicate fibrous tissue. Acid-fast stains show considerable variation in the number of organisms at this stage. When they are present, globi are less frequently seen than in the preceding stage. These are present in the interstitial tissues in close relationship to the interstitial capillaries.

Obliterative Phase.—Again all degrees of gradation can be seen from the preceding phase to this final picture of complete fibrosis. Every microscopic field examined reveals the normal pattern to be replaced by a homogeneous fibrosis (fig. 4). No outline of seminiferous tubules can be detected, and vascularity is greatly diminished and almost limited to very small capillary-sized vessels. Acid-fast organisms, globi, and lymphocytes are almost uniformly absent.

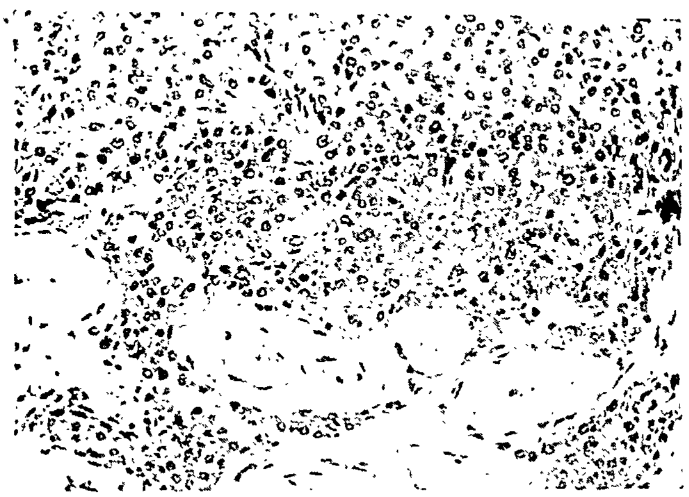

Fig. 3.—Aggregations of Leydig cells and atrophic seminiferous tubules in which a few Sertoli cells may be seen; acid-fast stain is negative (hematoxylin and eosin × 83).

Special stains of testis, epididymis, and ductus deferens for amyloid have been uniformly negative despite the fact that renal, adrenal, hepatic, and splenic amyloidosis is found in 65% of male patients studied postmortem. It appears that there is minimal vascular involvement of the epididymis during the bacteremia. Organisms, lymphocytic infiltration, and fibrosis of a lesser degree than in the testis are present in the epididymis. Giant cells, described by Young as being characteristic of leprous orchitis, have not been observed in our series.

PATHOGENESIS

Several features of the pathological picture are enigmatic. However, it can be stated with certainty that there is some degree of orchitis, or its residuals, in every male patient examined postmortem in this laboratory. At present it is difficult to correlate degree of atrophy with the age of the patient, or with duration or severity of disease.

It is remarkable that in leprosy the testis is so frequently involved and that in no other infectious disease process is there a quite comparable testis specificity. Obviously inherent physiological characteristics of the gonads or common embryological ancestry of the organs is of no significance, for the ovaries are not involved in any female patients studied postmortem in our series. It may be postulated that the environmental temperature difference between testis and ovary may account for this finding.

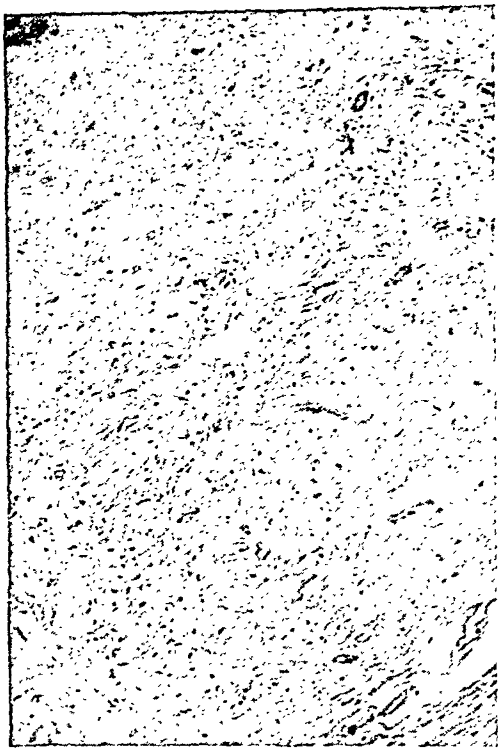

Fig. 4.—Complete fibrosis of testis; acid-fast stains negative (hematoxylin and eosin × 150).

The pathogenesis of leprous orchitis and final atrophy appears to be a transition from an active, acute lepromatous orchitis to a final picture of complete atrophy of the testis with obliteration of all landmarks by fibrous tissue. It is presumed that the initial lesion is infiltration of the vessel walls and adjacent tissue by Myco. leprae. There is a concomitant lymphocytic reaction, and large numbers of acid-fast organisms are seen. The bacteria are present in typical aggregates as elsewhere in the body. Next is seen a focal and, finally, a complete disappearance of germinal cells, with replacement by a syncytium of Sertoli cells, which completely fill the lumens.

The interstitial tissues appear to be next involved. There is often rather striking clumping of interstitial cells. It is doubtful that there is a true interstitial cell hyperplasia. Myco. leprae have not been demonstrated during this stage. Apparently, by a process of fibrosis, the final phase is a complete disappearance of Leydig cells and seminiferous tubules, with terminal obliterating endarteritis. It has been observed in our group that adrenal amyloidosis is found in all subjects whose testes exhibited interstitial cells in larger than normal numbers. The exact significance of this is not known.

CLINICAL FINDINGS

The duration of known leprosy in these patients, whose ages were between 17 and 79 years, was six months to 50 years. Of 50 testes measured in 25 patients, 14 (28%) were atrophic on the basis of measurements below 3.0 by 2.0 cm. (normal, 4.5 by 2.5 to 3.5 by 2.0 cm.). It has been observed that atrophy is almost always bilateral. In many instances the presence of rather large hydroceles, which is not unusual in this group of patients, has made it difficult to obtain accurate measurements. It has been our impression that testis atrophy is far commoner in patients with the lepromatous type than in those with the tuberculoid type of leprosy. Gynecomastia was present in 32 of 179 patients (19%) (fig. 5). It is obvious that many patients observed to have testis atrophy had no gynecomastia. In only one patient was the height-span measurement suggestive of a eunuchoid stature. There were no voice changes except in a 65-year-old patient suspected of having leprous laryngitis. Thyroid cartilage was normal in all subjects examined.

It is difficult to evaluate the shaving habits accurately in this group of patients. Many were Negroes from the Virgin Islands, who characteristically had a scanty beard. Many nonleprous patients reportedly shaved only once or twice weekly. There was no history of impotence in the group, and ejaculations in all were apparently normal. Sperm cell counts were not made. There was scanty trunk distribution of hair in 8 of 25 patients and sparse axillary hair in 5 of 25. It must be remembered, however, that leprosy in itself produces changes associated with decrease in body hair. In general, then, these patients have not had classical eunuchoid character

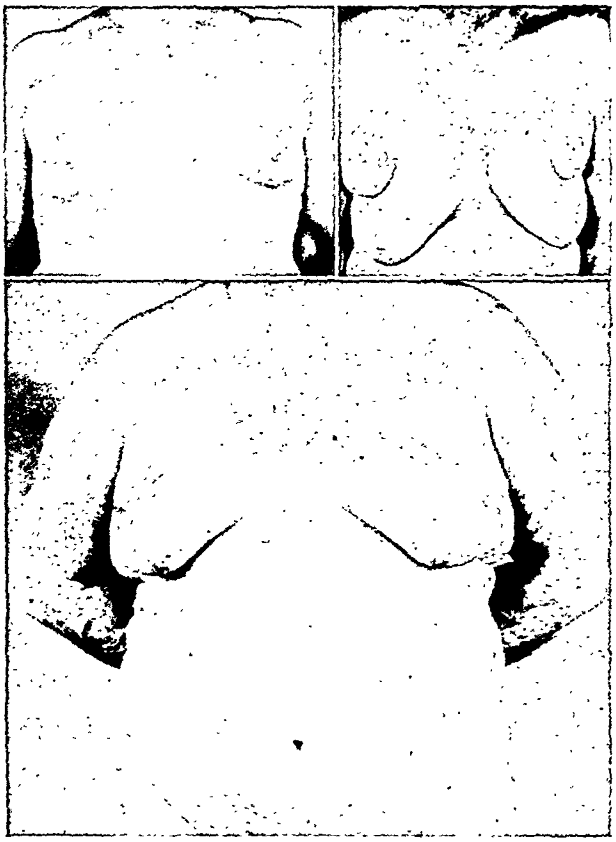

Fig. 5.—Types and degrees of gynecomastia.

A history of orchitis was obtained in 9 of 25 patients with atrophy, an incidence of 36%. This figure is rather high, and it is suggested that in many epididymitis, and not true orchitis, is the significant lesion. The sizes of testes varied from 4.7 by 3.0 to 1.7 by 1.4. These testes are not so small as to be immeasurable and are, therefore, slightly larger than those described in the group with the Klinefelter syndrome.[10]

The 17-ketosteroids were normal (7.8 and 9.7 mg. per 24 hours), and gonadotropins were markedly elevated (less than 288 and more than 384) in two subjects, only one of whom had gynecomastia. In the method utilized in these determinations no attempt is made to separate follicle-stimulating hormone and luteinizing hormone, and they are reported at total gonadotropins.

COMMENT

It is important to differentiate the terms "testis atrophy" and "hypogonadism" or "hypogenitalism." Whereas not all subjects with atrophic testes show overt manifestations of clinical hypogonadism, the vast majority with hypogonadism have either atrophic or completely absent testes (true eunuchism).

Rolnick [11] uses the term "primary hypogenitalism" to denote deficiency of pituitary gonadotropic factor with secondary testis failure. The more accepted terminology reserves the term "primary hypogonadism" for conditions involving intrinsic testis defects of either seminiferous or of interstitial cell elements. Secondary hypogonadism then implies the failure of either the production or the release of gonadotropic hormones. The classical causes of testis atrophy are legion and include cryptorchism; direct trauma; surgical trauma, as following orchiopexy or other scrotal surgery; vascular lesions, including infarction or torsion; senility; mumps; prolonged hyperpyrexia; debility; irradiation; avitaminosis; cirrhosis; schizophrenia; hypothyroidism; diethylstilbestrol therapy; diseases of the pituitary and hypothalmus; pseudohermaphroditism and true hermaphroditism; and inflammatory lesions, including leprosy. The atrophic testis is as vulnerable to secondary disease processes as is the normal testis. Seminoma and interstitial cell tumor formation have both been described in atrophic testes.[12] Secondary disease processes in the testes of those with clinical hypogonadism, however, have interestingly enough not been described.

In 1942 Klinefelter, Reifenstein, and Albright [10] reported in some detail a syndrome characterized by hyalinization of seminiferous tubules in small testes, aspermatogenesis, gynecomastia, normal Leydig cells, normal or decreased 17-ketosteroids, and increased follicle-stimulating hormone. These findings were described in nine subjects. Heller and Nelson [13] in 1945 described a similar entity. These authors studied 20 patients within a period of one year and had 30 additional cases over this same period that were not reported. They stressed the frequency of this syndrome. Three constant features of the syndrome were described by Heller and Nelson as (1) small testes, (2) azoospermia, and (3) high level of gonadotropins. Nine variable features were referable to skeletal changes, gynecomastia, external genitalia, hair distribution, pitch of voice, muscular development, Leydig cell appearance, 17-ketosteroid excretion, and excretion of estrogens. After a comparison of these features with those observed in the subjects described herein, it is apparent that we are dealing with what seems to be a very similar disease process. We have observed atrophic hyalinized testes, normal levels of 17-ketosteroids, elevated levels of gonadotropins, and gynecomastia, the more constant features. Perhaps leprosy is one of the known causes of this syndrome characterized by hypergonadotropic eunuchoidism.

An often neglected, yet important, phase of studies of testicular atrophy is associated liver disease. In 1926 Corda [14] reported a case of hepatic cirrhosis with associated testicular atrophy and gynecomastia. Since that time many similar reports have been described. Bennett, Baggenstoss, and Butt [15] have recently reported the study of another group of cirrhotic patients with testicular atrophy and gynecomastia. It has been suggested that in patients with severe liver disease, including cirrhosis, the normal inactivation of estrogen is interfered with and increased amounts are responsible then for such changes as gynecomastia. There appears to be no consistent correlation between liver damage and testicular atrophy in our series, in that cirrhosis has not been observed at any of the autopsies.

That any of these syndromes may exist without all the factors that go into its composition does not seem unreasonable. As Heller and Nelson remark in their study, "Because they lack gynecomastia these cases cannot be regarded as examples of the syndrome as originally described (by Klinefelter et al.); yet we hesitate to call these cases examples of a new and separate syndrome." The same might be applicable to these patients with leprosy. We agree with Heller and Nelson and believe that these may be a part of a rather large group of hypergonadotropic eunuchoids, and we hesitate to create a new name for the condition in these cases.

It is known that the testis produces two definite hormones: testosterone and estrogen. It is not within the scope of this paper to discuss the matter of a third hormone of the testis. Briefly it has been postulated that the Sertoli cells of the seminiferous tubules or the germinal epithelium itself produces an "x-hormone," called variously "inhibin" or "contruin," which is a pituitary antagonist. The functions of this second hormone include the inhibition of production of follicle-stimulating hormone, the support of spermatogenesis, and inhibition of the mammotropic hormone. With an absence of this hormone as would of necessity occur with hyalinization of the seminiferous tubules, there is then an increase in production of follicle-stimulating hormone, azoospermia, and gynecomastia. It should be noted that there are several good theories that militate against the presence of a third hormone. One such theory (Heller and Nelson) is that the elevated gonadotropins result from failure of the seminiferous tubules to utilize follicle-stimulating hormone.

No specific therapy has been undertaken for the testicular atrophy or gynecomastia per se. Since this group of patients possibly fits into the group of hypergonadotropic eunuchoids, it is not likely that pituitary hormone in any form would be of avail. Heller and Nelson have reported favorable response in their group to substitution androgen therapy. This may be of some value in patients with leprosy, but it has not been tried to date.

SUMMARY AND CONCLUSIONS

Genitourinary tract involvement in patients with leprosy is briefly described. One hundred seventy-nine male patients with leprosy (Hansen's disease) were examined with respect to atrophy of the testes and gynecomastia. Twenty-eight per cent were found to have atrophy, and 19% were found to have gynecomastia. In addition, a histological study of the testes of 20 subjects with leprosy is reported. This includes material from autopsy and surgical biopsy. A rather characteristic picture of leprous orchitis with infiltration of the vessel walls and adjacent tissues by Mycobacterium leprae, interstitial cell clumping, and atrophy of seminiferous tubules progressing to complete fibrosis and obliterating endarteritis is described. The 17-ketosteroids were normal and gonadotropins were increased in two of the subjects whose testes were subjected to biopsy.

It is suggested that this group of patients, despite their not presenting typical eunuchoid features, fits into the general category of hypergonadotropic eunuchoids described by Klinefelter, Reifenstein, and Albright and by Heller and Nelson, with characteristic atrophic testes, normal 17-ketosteroids, elevated level of gonadotropins, and gynecomastia. It is postulated that leprosy is perhaps one of the few disease entities of this group in which the etiological factors are known.

RECURRENT LEFT LARYNGEAL NERVE PARALYSIS IN ARTERIOSCLEROTIC HEART DISEASE

Samuel Zelman, M.D.
and
Gerald William Nice, M.D., Topeka, Kan.

Hoarseness due to recurrent left laryngeal nerve paralysis is a rare occurrence in patients with congestive heart failure of any cause but is most commonly seen with severe mitral stenosis, and less commonly with congenital heart disease,[1] when marked dynamic dilatation of the left pulmonary artery compresses the nerve against the aortic arch, its adjacent lymph nodes, and the ligamentum arteriosum.[2] It is extremely uncommon in patients with arteriosclerotic heart disease, having been reported previously only by King, Hitzig, and Fishberg.[3]

REPORT OF A CASE

A 55-year-old white male married engineer was first admitted to Winter Veterans Administration Hospital Aug. 12, 1948, complaining of short attacks of substernal pressure-like pain, occasionally radiating down both arms, during the previous two winters. He had also noticed easy fatigability and shortness of breath on exertion since February, 1948. This became severe and accompanied by nocturnal dyspnea in June, 1948. Since that he had been treated with digitalis, with improvement. For the two years prior to examination his voice would break occasionally for a few seconds at a time. On June 1, 1948, he awoke in the morning with hoarseness, which remained until the time of admission.

At the time of physical examination the patient was in no distress. His blood pressure was 110/90. His pulse was regular, with a rate of 72. The heart tones were somewhat faint, and there were no murmurs. The lung fields were clear to auscultation and percussion. The peripheral vessels were not remarkable. There was no cyanosis, edema, or clubbing. Laryngeal examination revealed complete paralysis of the left vocal cord. The arm to tongue circulation time (tested with dehydrocholic acid) was 27 seconds. The chest roentgenogram revealed enlargement of the left ventricle. Fluoroscopic examination of the mediastinum revealed no apparent cause for pressure on the left recurrent laryngeal nerve. The patient was fully digitalized, with prompt relief of dyspnea.

After discharge from the hospital on Aug. 30, he continued to take digitoxin for seven months, without shortness of breath. His hoarseness began to diminish at the time of discharge and completely disappeared five weeks later. Seven months after he left the hospital he stopped taking digitoxin on the advice of his family physician. Six weeks prior to his second admission, on July 29, 1951, he began to notice gradually progressive weakness, orthopnea, and nocturnal dyspnea and his hoarseness returned. He consulted a laryngologist, who found "inflammatory laryngitis" and referred him to an internist, who advised hospitalization.

Physical examination on the second admission revealed the patient to be dyspneic and in obvious respiratory distress. There was no distention of the neck veins. There were moist rales at both lung bases, with some dulness and diminished breath sounds at the base of the right lung. The blood pressure was 130/90. The pulse was regular, with a rate of 96. The heart sounds were distant, and no murmurs were heard. The liver edge was palpable 2 cm. below the costal margin and was not tender. There was no ankle edema. Laryngeal examination revealed complete paralysis of the left vocal cord.

Results of routine hematologic studies, including the sedimentation rate, were normal. Urinalysis and serologic studies disclosed no abnormalities. The serum cholesterol was 341 mg. per 100 cc. The plasma chlorides were 95 mEq. per liter, and carbon dioxide was 45 vol. %. The basal metabolic rate was +1%. A chest roentgenogram revealed obliteration of the right costophrenic angle, with a uniform density over the lower third

of the right lung. The heart appeared enlarged to the left, and there was some widening of the aortic arch. A chest roentgenogram on Aug. 10 revealed clearing of the right lung base. Electrocardiograms revealed left bundle branch block. The arm to tongue circulation time (tested with dehydrocholic acid) was 30 seconds; ether circulation time was 9 seconds. The vital capacity was 4.6 liters (99% of normal).

Fluoroscopic examination revealed moderate elongation of the left ventricular inflow and outflow tracts, with some hilar congestion and moderate posterior bowing of the esophagus by enlargement of the left auricle. An unusually low aortic arch was seen in the left anterior oblique view to encroach on the aortic window close to the left pulmonary artery.

Digitoxin was again given to toxicity levels, because of the slow decrease in circulation time and the persistent pulmonary basal rales. Weakness, orthopnea, and nocturnal dyspnea improved within a few days after digitoxin therapy was started. However, dyspnea on exertion persisted. At the time of discharge on Oct. 27, his hoarseness had begun to improve.

Sudden death, presumably a result of coronary occlusion, occurred Jan. 2, 1952. No autopsy was performed.

COMMENT

The primary cardiac strain in patients with arteriosclerotic heart disease is nearly always on the left ventricle, in contrast to the primarily left auricular strain imposed by mitral stenosis. Only when the arteriosclerotic left ventricle fails does increased pressure occur in the left auricle and pulmonary vessels. The right ventricle does not, as in patients with mitral stenosis, enjoy a prolonged period of adjustment to the increased strain. When failure of the left ventricle occurs, it is apt to be of relatively rapid onset, or intermittent in character, as in paroxysmal nocturnal dyspnea or exertional dyspnea, with sudden imposition of strain on the right ventricle.

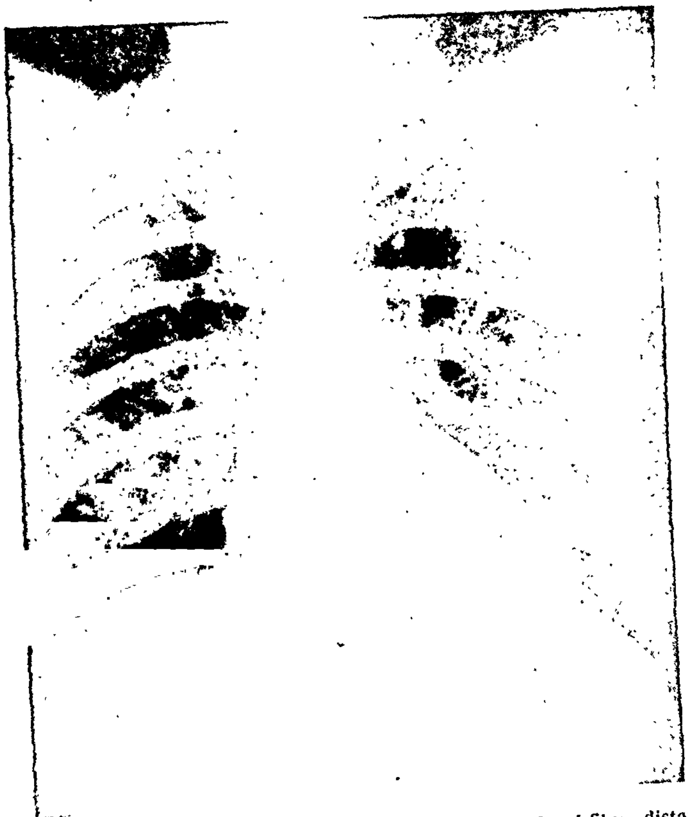

Fig. 1.—Posteroanterior view of the chest, 6-ft. focal-film distance. Note the low position of the aortic knob, elongation of the left ventricular outflow tract, and pulmonary congestion.

The extreme degree of chronic pulmonary congestion often seen with mitral stenosis is rare in patients with arteriosclerotic heart disease. The right ventricle fails more rapidly in the latter, with consequent relief of pulmonary hypertension. If dynamic dilatation of the left pulmonary artery is the common basis of recurrent laryngeal nerve compression, one would not, therefore, expect its occurrence other than rarely in patients with arteriosclerotic heart disease.

In our patient, left ventricular failure had been continuous, though varying in degree, for nearly four years. At no time had right heart failure appeared. In this respect he resembles patients with mitral stenosis, in having had prolonged pulmonary congestion and right heart strain. This is evident not alone in his symptomatic history and physical examination findings, but also in his circulation times, which had persistently shown relatively normal right heart (arm to lung) times with markedly prolonged left heart (lung to tongue) times. Digitalization even to toxicity, low-salt intake, and treatment with mercurial diuretics had not relieved entirely his left heart failure; insofar as relief was achieved, the hoarseness and vocal cord paralysis cleared repeatedly.

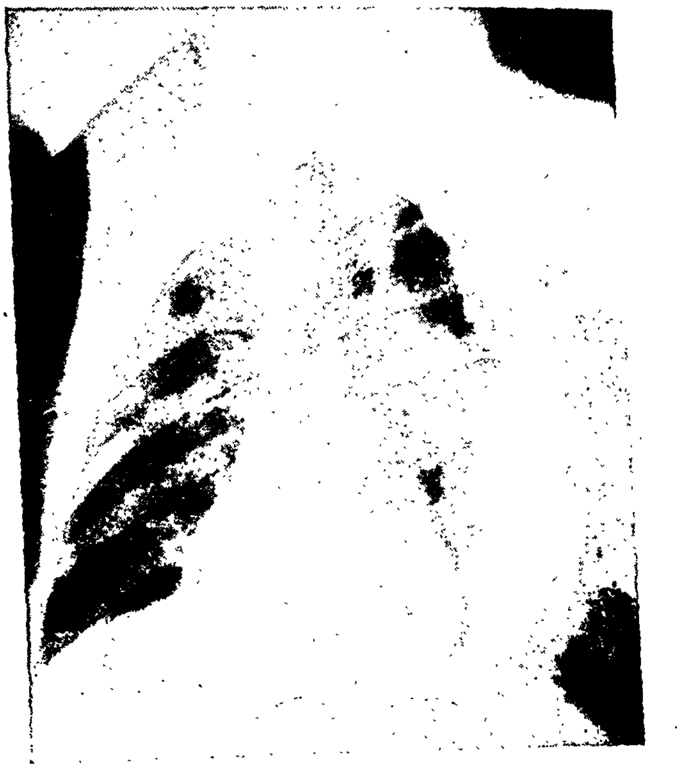

Fig. 2.—Left anterior oblique view of the chest, 6-ft. focal-film distance. Note the low position of the aortic arch, almost completely obliterating the usual "aortic window" between it and the pulmonary artery. The inflow tract of the left ventricle is elongated and fails to clear the spine.

An additional factor in the recurrent laryngeal nerve compression in this case may well have been the unusually low position of the aortic arch in relation to the left pulmonary artery. This was evident in the low position of the aortic knob seen on the roentgenogram (fig. 1) and was confirmed on fluoroscopic examination. The low position of the transverse portion of the aortic arch was seen to reduce sharply the vertical diameter of the "aortic window" in the left anterior oblique view, very nearly obliterating it (fig. 2). Very little pulmonary artery dilatation would, in this circumstance, suffice to compress the recurrent nerve against the aorta.

SUMMARY

The rare occurrence of left recurrent laryngeal nerve paralysis with arteriosclerotic heart disease is reported and its pathogenesis discussed. It is suggested that an unusually low transverse aorta encroaching on the "aortic window" was partially responsible for the nerve compression in the case reported.

for two more days. A total of 14 capsules had been given. About a week later, (April 19 or 20) the man again had taken 1 capsule every four hours for 4 doses.

On April 22, jaundice had been noted and four days later the patient had been admitted to his local hospital. In the history taken at that time it was recorded that he had "become ill a week ago after eating a ham salad sandwich, and had nausea, vomiting and vertigo." (This was the time of his second course of chloramphenicol.) Following the episode related in the quotation, the nausea and anorexia had persisted, along with the developing jaundice.

Results of laboratory work done at his local hospital were reported as follows:

The hemoglobin value was 99.5%. There were 5,190,000 erythrocytes and 5,850 leukocytes. A differential leukocyte count revealed 45% lymphocytes, and 54% neutrophils. The icterus index was 29.2. A van den Bergh test revealed 3.8 mg. of bilirubin per 100 cc. by direct reaction. The prothrombin level was 79%. The sedimentation rate was 12 mm. per hour (Westergren). Tests of stools for occult blood were negative. Serologic tests for syphilis were negative. Gastrointestinal roentgenograms revealed no gross abnormalities, and the comment was "liver and spleen shadows appear within normal limits."

In his referring letter the attending physician commented: "Our impression was that he had a toxic hepatitis." The patient stated "the jaundice cleared 100% in three days" and said that he had felt well thereafter.

The man came to the Mayo Clinic for examination and was admitted on the date given at the start of the report of this case, about two weeks after his dismissal from his local hospital. The only abnormalities found on physical examination were a few petechiae where his shoulders had rubbed on the back of the seat of the automobile while traveling, petechiae about the waist where his belt had rubbed, and other petechiae on the legs and ankles. The patient had not noticed the petechial spots. Laboratory work at this time gave the following results:

Urinalysis revealed red blood cells, grade 2. The hemoglobin level was 13.4 gm. per 100 cc., and there were 4,400,000 erythrocytes and 5,800 leukocytes. The differential leukocyte count revealed 49.5% lymphocytes, 2% monocytes, 47.5% neutrophils, and 1% basophils. There were 18,000 thrombocytes. The report on the blood smear was "Marked thrombocytopenia; some increase in lymphocytes; no immature forms were seen." There was no serum bilirubin on the direct test, with a level of 1.2 mg. per 100 cc. revealed by the indirect test. The flocculation test for syphilis was negative. The prothrombin time was 19 seconds. In a liver function test with sulfobromophthalein (bromsulphalein®) there was no dye retention in one hour.

A chest roentgenogram revealed no abnormalities. A gallbladder roentgenogram showed a normally functioning gallbladder. Volumetric study of aspirated bone marrow material revealed only a 1% nucleated cell layer. The report of smears of bone marrow read, "All elements are reduced. Megakaryocytes are virtually absent. The majority of the cellular elements are lymphocytes and plasmacytes." The description of fixed sections of the bone marrow stated that there were "small units which show the structure of a hypocellular marrow. Lymphocytes are the predominant cell."

In our opinion aplastic marrow was developing in this case, and the patient was dismissed with the advice to be under constant observation at home and to receive transfusions as he might need them. During the period June 25 to 30 inclusive, laboratory findings at the patient's home were essentially the same as those just noted. In this same period he received transfusions of 3 pints (approximately 1,500 cc.) of blood.

On July 1, the man was seen at another medical center and the physicians there supplied the following data: There were 2,400,000 erythrocytes, and 4,000 leukocytes. On a differential leukocyte count there were 55% lymphocytes, 5% monocytes, and 40% neutrophils. On blood smears the cells were qualitatively normal in appearance. Sternal aspiration revealed "markedly acellular bone marrow with only a rare normoblast and no megakaryocytes seen." There was, however, a "fair representation of myeloid cells." In view of these findings, it was suggested that cortisone might be used in addition to treatment by transfusion.

Following the patient's return home, bleeding continued, and he was admitted in emergency condition to another hospital on July 28. His attending physician and the staff pathologist have reported the findings of his final hospitalization. Physical examination disclosed the presence of multiple petechiae and ecchymotic lesions of the skin, as well as multiple areas of bleeding and ulceration in the mouth, including the gums. There was tenderness of the left lower extremity. (This raises the question whether there was hemorrhage into the muscles.)

Results of laboratory work done on July 28 were reported as follows:

The hemoglobin level was 9.2 gm. per 100 cc. There were 2,850,000 erythrocytes, and 2,400 leukocytes, with 96% lymphocytes, 2% monocytes, and 2% neutrophils. There were 19,000 thrombocytes. The coagulation time was seven minutes and four seconds, and the bleeding time was two and one-half minutes (?). The prothrombin time was 68% of normal.

The patient had moderate elevation of temperature while in the hospital. Terminally Cheyne-Stokes respiration developed, and the man died four days after his admission. Significant findings at necropsy included considerable blood in the subarachnoid space, as well as evidence of hemorrhage in other organs. The liver, spleen and lymph nodes appeared grossly normal. Microscopically, the structure of the liver and the spleen seemed undisturbed. Concerning the bone marrow, the report was, in part, as follows: "Its cellularity varies considerably in different areas. In some, the marrow is found to be quite cellular while, in others, it is largely fatty. We fail to see megakaryocytes. Erythroid and myeloid elements also seem to be diminishing."

Case 3.—This white girl, 3 years of age, was admitted on March 19, 1951, because of severe bleeding. She had had repeated infections of the upper respiratory tract but otherwise her past history and family history were not remarkable. Three siblings were living and well.

About five weeks before admission she had had acute pharyngitis and had been treated with "about 20 capsules of chloromycetin® during the three weeks" before the onset of her hemorrhagic tendency. Two weeks before admission, petechiae and ecchymotic areas had developed on the body. "Some penicillin and vitamin K" were given at this time. Severe and persistent epistaxis had appeared and repeated transfusions of blood, totaling 1,250 cc. had been administered. Studies of blood and bone marrow had indicated that the girl had hypoplastic anemia.

At the time of admission to the Mayo Clinic, the patient was acutely ill; her temperature was 103 F. Physical examination revealed multiple petechiae and ecchymotic areas and the girl was actively bleeding around the nasopharyngeal pack, which was in place at the time of her admission. Adenopathy or other abnormalities were not noted.

Laboratory studies made while she was in hospital in Rochester revealed the following:

The results of urinalysis were normal. The hemoglobin level decreased from 15.5 to 9.2 gm. per 100 cc. The erythrocytes decreased from 5,030,000 to 2,710,000, and the leukocytes from 1,700 to 600, with lymphocytes increasing from 95 to 97%, monocytes from 1 to 3%, and the neutrophils from 1 to 2%. The thrombocytes varied from 5,000 to 22,000. There were 0.1% reticulocytes. Blood smear revealed marked neutropenia and thrombocytopenia. The blood urea level was 32 mg. per 100 cc. The prothrombin time was 21 seconds. A chest roentgenogram revealed no abnormality. Volumetric study of aspirated bone marrow material revealed a myeloid-erythroid layer of only 1%.

The patient was in the hospital for nine days. The course of the illness was stormy, and her temperature ranged from 99 to 104 F. Treatment consisted of four blood transfusions of 250 cc. each. By mouth, each day, the patient received 750 mg. of aureomycin, as well as 100 mg. of cortisone. She died on March 27, from massive gastrointestinal hemorrhage.

Necropsy revealed markedly hypoplastic bone marrow, with little evidence of hematopoiesis. There was a relative increase in reticuloendothelial cells and lymphocytes. Hemorrhages were numerous and diffuse in many viscera, and moniliasis of the esophagus, stomach, spleen and kidneys was observed.

CASE 4.—This white girl, 5 years of age, was admitted on Dec. 6, 1951, with a chief complaint that purpura had been present for four weeks. A subordinate complaint was of chicken pox of four days' duration. The girl had had the usual infections of childhood. Her past history and her family history were not remarkable.

Four weeks before admission, bruises, which were unusual for her, had appeared. About a week later noticeable irritability had developed, and she had begun to have spontaneous epistaxis. By the time another week had passed, definite petechiae had appeared. Rutin and vitamin K had been given at this time. During this period, the patient's 8-year-old brother had had chicken pox and, on Dec. 2, the patient and her 6-month-old brother both had displayed the first signs of chicken pox. By the evening of Dec. 3, the vesicles of chicken pox had appeared on the girl's body and had become hemorrhagic. Meanwhile her temperature became elevated. The temperature ranged from 103 to 105 F until the time of admission to the hospital in Rochester. On Dec. 3, she had received aureomycin, 150 mg. every four hours, and 300,000 units of penicillin twice a day. On Dec. 4, she had vomited blood-streaked material and administration of aureomycin had been discontinued. The daily dose of penicillin had been increased to 1,000,000 units on Dec. 5.

On Dec. 4, the concentration of hemoglobin had been 11.6 gm. per 100 cc. of blood. Erythrocytes had numbered 3,360,000 and leukocytes 1,240 per cubic millimeter of blood.

The patient had received 18 capsules of chloramphenicol of 50 mg. each in late August, 1951. In October of the same year, also, she had been given *p*-benzylphenyl carbamate ("diphenan"), 0.25 gm. three times a day for seven days, for pinworms.

On physical examination in Rochester, the child appeared to be alert but acutely ill. A severe, hemorrhagic, vesicular rash extended "from head to toe." The lesions varied from ordinary maculae to hemorrhagic vesicles, 3 mm. in diameter, with numerous associated petechiae and ecchymotic areas. The gums were bleeding, and there were numerous small areas of hemorrhage and ulceration in the mouth and pharynx. Adenopathy worthy of remark and hepatosplenomegaly were not found. The temperature was 103 F and a pulse rate of 110 per minute was charted.

Laboratory findings were as follows: The urinalysis revealed no abnormalities. The hemoglobin level was 8 gm. per 100 cc. There were 3,080,000 erythrocytes, and 3,200 leukocytes, with 91% lymphocytes, 2% monocytes, and 7% neutrophils. There were 41,000 thrombocytes. The bleeding time was 14½ minutes. The sedimentation rate was 72 mm. per hour (Westergren). There were from 0.3 to 1.1% reticulocytes.

The report on the blood smear read, "Left shift and toxic changes in neutrophils seen. Moderate number of plasma cells with a few atypical lymphocytes. Very rare platelet seen. There is no myeloid immaturity found." Bone marrow obtained by sternal aspiration revealed, on volumetric study, no demonstrable myeloid-erythroid layer. In smears of the bone marrow there were an occasional normoblast and myeloid element. No megakaryocytes were seen, but a few platelets were encountered. The predominant cells were adult lymphocytes. Material for study of fixed sections was not obtained. A chest roentgenogram, made with portable apparatus, revealed conditions that were within normal limits.

The course of the illness for the 14 days while the patient was in hospital was satisfactory. Four blood transfusions and daily penicillin therapy were given for support. Meanwhile, the lesions of chicken pox cleared and the temperature fell to normal. The concentration of hemoglobin could not be maintained, however; after it had been raised from 7.2 gm. to 11 gm. per 100 cc. of blood, by means of transfusions, it was back to 8.4 gm. at the time of dismissal. The other blood values, on repeated reexamination, stayed essentially within the same range as those in the initial studies.

In the interval of four weeks while the patient was away from the clinic, she received two blood transfusions, one of 200 cc. and the other of 250 cc. When she returned on Jan. 22, 1952, the only remarkable features discovered on physical examination were many petechiae and ecchymotic areas, especially on the legs.

Laboratory work on this occasion gave the following results: The hemoglobin level was 9.4 gm. per 100 cc. There were 3,010,000 erythrocytes, and 4,800 leukocytes, with 65.5% lymphocytes, 12.5% monocytes, 21% neutrophils, and 1% eosinophils. There were 1% reticulocytes and 35,000 thrombocytes. The blood smear was said to be "essentially same as before."

On Feb. 19, the patient was again brought back to the clinic. In the interval during which she had been away, three more transfusions had been administered. Results of physical examination were negative except for the evidence of purpura.

Laboratory findings were as follows:

The hemoglobin value was 10.5 gm. per 100 cc. The erythrocyte count was 3,510,000 and the leukocyte count 3,700. A differential leukocyte count showed 87% lymphocytes, 6% monocytes, and 7% neutrophils. There were 0.5% reticulocytes and 27,000 thrombocytes. The report on blood smear stated: "Nothing changed over previous reports." Studies of bone marrow obtained on sternal aspiration gave the same results as on the previous occasion.

The final episode of the illness of this patient began on April 1 and terminated 24 hours later with death from cerebral hemorrhage. Her condition had remained essentially unchanged since we had last seen her; she had been active and had felt well most of the time. At 3 a. m. she awoke with a headache and about one and a half hours later started to vomit blood. Throughout the day hematemesis recurred, and, by evening, further signs of cerebral bleeding were developing. She had repeated convulsions until she died.

CASE 5.—This child was not our patient but was a playmate of the girl in case 4. We feel that a brief report of her case should be included in this series for reasons that will become apparent. The physician in the two cases was the same, and he provided the data in this case as well as those parts of the data in case 4 that were gathered elsewhere than in Rochester. The illnesses of the two little girls ran nearly identical courses.

This patient (case 5) received a total of 42 capsules (50 mg. each) of chloramphenicol. These were administered in doses of 100 mg. every six hours from Oct. 13 through Oct. 19, 1951. A careful review of the case with the parents of the child verified the physician's belief that the parents gave no other medication and that the only drug both children had received was chloramphenicol; in other words, *p*-benzylphenyl carbamate was not a factor in this case (case 5).

Aplastic anemia developed, and the course of the illness was the same as that in case 4. The cause of death was cerebral hemorrhage. To quote from the letter of the physician: "Her drug (chloromycetin®) was started about six weeks after Mary's [11]—her purpura appeared on Dec. 18, about six weeks after Mary's and her death came six weeks after Mary's."

CASE 6.—A white girl, 13 years of age, was admitted to the Mayo Clinic on April 8, 1952, complaining of bleeding. The family history was essentially negative; there were three siblings, living and well. There was a personal history of measles at the age of 9 years; of mumps in June, 1951; of appendectomy in November, 1951, and of chicken pox in March, 1952.

The significant part of the history of her present illness goes back to Jan. 26, 1951, when, in her home community, chloramphenicol had been given to her father and the patient had taken 4 capsules (not at the same time) for the "flu." She had not displayed any signs of reaction.

At the end of February, 1952, 13 months later, the patient again had had the "flu." The capsules of chloramphenicol still had been in the house, unused, and the girl had been given 1 capsule at a time for 4 doses.

On March 1, the patient had undergone dental extraction and a dental penicillin-sulfonamide pack had been used. On March 26, petechiae had developed over the feet and limbs. On April 2, a "sore" had appeared on the lower lip and ecchymosis and petechiae had been generalized. On April 4, protracted epistaxis had occurred, and the girl had been admitted to a hospital where laboratory work had revealed a "leukocyte count of 2,200 and no granulocytes present." A blood transfusion of about 500 cc.

---

[11] Mary is the name representing the patient in Case 4, but is not the real name of the patient.

had been given on each of the three following days (April 5, 6 and 7), and the girl had been brought to Rochester where she was admitted directly to hospital.

The patient was normally developed and nourished but petechiae and ecchymotic areas were extensive. The gums were swollen and slightly hemorrhagic, and there was an ulcerated area, 1 cm. in diameter, on the lower lip. Results of the rest of the physical examination were not remarkable. The spleen was not palpable, and adenopathy was not noted. The girl's temperature was 101 F.

Laboratory findings were as follows:

Urinalysis revealed no abnormalities. The hemoglobin level was 14.6 gm. per 100 cc. There were 4,030,000 erythrocytes and 1,400 leukocytes. Differential leukocyte count revealed 94% lymphocytes, 2% monocytes, 2% neutrophils, and 2% eosinophils. There were 51,000 thrombocytes and 0.1% reticulocytes. The bleeding time was 15½ minutes, and the prothrombin time 17 seconds.

The report of the blood smear read, "Only one granulocyte is seen and no immature forms of any type of cell are found. The platelets are considerably reduced on the preparation." Aspirated bone marrow, on volumetric study, yielded a myeloid-erythroid layer of only 1%, while in all smears of bone marrow small lymphocytes predominated. There were some plasmacytes, reticuloendothelial cells, and a rare myeloid-erythroid element among the lymphocytes. In fixed sections there was only fatty marrow containing an occasional nest of cells.

During the period of hospitalization, the course of the illness was septic and the temperature ranged from 100 to 105 F. Acute otitis media yielded material from which Escherichia coli were cultured. After studies to detect sensitivity had been made, the patient was given 0.5 gm. of dihydrostreptomycin intramuscularly twice a day, in addition to 1,000,000 units of penicillin (duracillin®) daily, to protect her in her agranulocytic state. She also received 18 blood transfusions of 500 cc. each, given as they were indicated for bleeding. Cortisone also was given in increasing doses, to 300 mg. daily (intramuscularly), then the quantity was reduced to a maintenance dose of 100 mg. (50 mg. twice a day). When it became evident that the girl's condition was not improving with the help of cortisone, corticotropin was employed and its use was continued for the last four days of her life.

Throughout the 22 days that the patient was in hospital, leukocytes varied in number from 600 to 1,500 per cubic millimeter of blood, 99 to 100% of which were lymphocytes. Thrombocyte counts continued to be below bleeding levels at all times, ranging from 16,000 to 35,000 per cubic millimeter of blood. The cause of death was hemorrhagic pulmonary edema and gastric hemorrhage.

At necropsy, significant findings were: widespread hemorrhage of the viscera, focal necrosis and organizing bronchopneumonia of the right upper pulmonary lobe and terminal hemorrhagic edema of the lungs. Microscopic examination disclosed severe hypoplasia of the bone marrow, with little or no evidence of hematopoiesis.

Case 7.—A 36-year-old man was admitted to the Mayo Clinic on Feb. 25, 1952, because of a diagnosis, made elsewhere, of hypoplastic anemia with thrombocytopenic purpura. His own past history was not remarkable. His father had Raynaud's disease and diabetes. A sister had died with leukemia, and he had six siblings living and well.

The history of his present illness dated back to June, 1951, when he had had the "flu." He had received penicillin, which had given him hives. In July of the same year, Raynaud's phenomenon had developed in his hands. He had been hospitalized in October for 14 days with pneumonia and had received aureomycin for 10 days and chloramphenicol for 3 days. "His leukocyte count was 4,500 (per cubic millimeter of blood) but the remaining blood picture was normal"; this is the only hematological information we have concerning that illness.

Left cervicothoracic sympathectomy had been performed on Nov. 6 for the persistent Raynaud's phenomenon. Postoperative pleural effusion had developed, and again he had been given chloramphenicol and aureomycin. On Jan. 10, 1952, right cervicothoracic sympathectomy had been performed, at which time the concentration of hemoglobin had been found to be 9.2 gm. per 100 cc. of blood. He had had considerable trouble with bleeding from the nose, the gums, and the wound. Again he had received postoperative treatment with chloramphenicol and aureomycin.

On Jan. 22, he had been readmitted to the hospital with purpura, that is, he had had petechiae and ecchymosis, epistaxis, and hemorrhages into the muscles of the thigh. A diagnosis of thrombocytopenic purpura had been made. The thrombocyte counts then had been 15,000 and 25,000, while studies of the bone marrow had revealed the presence of hypoplastic anemia. Corticotropin had been administered, without benefit, for about 20 days. He had received numerous blood transfusions.

On Feb. 25, the date that was mentioned at the beginning of the report of this case, the patient entered a hospital in Rochester. Laboratory data at this time were as follows:

Urinalysis revealed no abnormalities. The hemoglobin level was 10.2 gm. per 100 cc. There were 3,350,000 erythrocytes and 2,600 leukocytes. The differential leukocyte count revealed 64% lymphocytes, 5% monocytes, 30% neutrophils, and 1% basophils. There were 0.1% reticulocytes and 50,000 thrombocytes.

A blood smear showed leukopenia with toxic neutrophils and marked thrombocytopenia. The bleeding time was more than 30 minutes. The sedimentation rate was 84 mm. per hour (Westergren). Aspirated bone marrow, on volumetric study, yielded a myeloid-erythroid layer of 2%, while study of smears of bone marrow revealed an occasional toxic granulocytic cell, a few normoblasts, but no megakaryocytes. The patient was dismissed five days after his admission with advice to continue with supportive blood transfusions. By correspondence we learned that he died six weeks after his dismissal.

Case 8.—This white woman, 70 years of age, was admitted to the Mayo Clinic for the fifth time on April 22, 1952. We first had seen her in 1939, when she was 58 years of age. At that time her chief complaint was symptoms of nervous tension. There also was a history of chronic discoid lupus erythematosus with onset in 1932, when the woman had been 51. The lesions had been confined to the scalp and face and had been well controlled by administration of quinine. In 1939, the woman weighed 175 lb. (79.4 kg.), and she had scars from past activity of her lupus erythematosus. Results of physical examination otherwise were not remarkable. Laboratory examinations at this time revealed values within normal ranges.

The woman came to the clinic for a second examination on April 21, 1944, at the age of 62 years. At this time her most significant complaint was urinary frequency of six months' duration, and she had been told that the urine contained pus, casts, and albumin. There were still evidence of her state of nervous tension. She weighed 166 lb. (75.3 kg.) and had alopecia and a blood pressure of 140 mm. Hg systolic and 82 diastolic. Examination of the eye grounds revealed incipient cataracts, grade 2 sclerosis, and grade 1 narrowing of the retinal arterioles, together with multiple, small retinal hemorrhages.

Results of laboratory studies made at this time were reported as follows:

The urine contained albumin, grade 1 to 2, red blood cells, grade 3 to 4, and pus, grade 1. The hemoglobin level was 11.2 gm. per 100 cc. There were 3,490,000 erythrocytes and 6,800 leukocytes. The flocculation test for syphilis was negative. Roentgenograms of the thorax and of the kidneys, ureter, and bladder revealed no abnormalities. The blood urea level was 72 mg. per 100 cc., and the creatinine level 2.3 gm. The urine culture was negative. Excretory urogram and cystoscopic examination revealed no abnormalities. A final diagnosis was made of chronic glomerulonephritis with renal insufficiency.

Our third experience with the patient was in November, 1944, when she was seen at home by one of our staff members in consultation with her home physician. At this time she was convalescing from bronchopneumonia and gave evidence of renal insufficiency and urinary infection. A prescription was given for sulfathiazole, 0.5 gm., three times a day, and a supportive regimen was advised.

She returned to the clinic on Jan. 3, 1949. In the five year interval her condition had not greatly changed. She did complain anew,* however, of very troublesome epigastric distress and increase in exertional dyspnea associated with some substernal distress. Three weeks before this visit she had been awakened with pain in the jaws and in both arms, for which she had been hospitalized. This distress had been recurring about five minutes after meals. Her blood pressure was 155 mm. Hg systolic and 86 diastolic. She was still obese but, otherwise, nothing remarkable was found on physical examination.

Laboratory work on this occasion disclosed the following:

The urine contained albumin, grade 1 to 3, and pus, grade 1 to 2. The specific gravity was 1.003 to 1.010. The hemoglbin level was 15.9 gm. per 100 cc. The erythrocyte count was 4,700,000 and the leukocyte count 7,700. The blood urea level was 58 to 84 mg. per 100 cc., and there was 7.3 mg. of sulfate per 100 cc. The *sedimentation* rate was 36 to 43 mm. per hour (Westergren). A roentgenogram of the stomach revealed "esophageal hiatal hernia with the cardiac third of the stomach above the diaphragm."

The patient was in the hospital for 37 days on a reduction regimen and conservative treatment for the diaphragmatic hernia was advised. In March, 1952, she had had increasing distress in the thorax and arms while at home. Her erythrocyte count had been 2,400,000 per cubic millimeter of blood and the value for hemoglobin, 9.2 gm. per 100 cc. of blood. Occult blood had been found in the stools. Treatment for peptic ulcer and repeated transfusions of 250 cc. of blood had been given. Results of laboratory work the next week had been reported as follows: There were 2,080,000 erythrocytes and 2,300 leukocytes. The hemoglobin level was 8.2 gm. per 100 cc. There were 65% lymphocytes. There were 43,000 thrombocytes. The stool contained occult blood. The sedimentation rate was 131 mm. per hour (Westergren). Studies of bone marrow had revealed "a hypoplastic marrow with an increase in plasmacytes."

The patient had received five transfusions, after which her erythrocyte count had been 3,200,000 per cubic millimeter of blood and the value for hemoglobin was 9.1 gm. per 100 cc. of blood. On April 22, 1952, as has been said, the patient returned to the clinic for further study, especially regarding the previously reported findings referable to the bone marrow. The pains in the thorax, jaw and arms were about the same as on previous visits. The patient repeated the nontechnical language in which her condition had been explained to her, saying that she had been told that she had a "weak bladder that did not empty well" (residual urine: 350 cc.) and that for the resultant urinary infection she had been receiving chloramphenicol. This drug had been given off and on for two years and, in the last six weeks, the dosage, while variable, "averaged 2 or 3 capsules a day, four or five days a week."

She was still moderately obese (150 lb. [68 kg.]) was pallid, and possibly was slightly icteric. The remainder of the physical examination was not productive of any evidence worthy of remark. Laboratory examinations revealed the following:

The urine contained albumin, grade 2, and pus, grade 1. The hemoglobin value was 11.3 gm. per 100 cc. There were 3,310,000 erythrocytes and 3,800 leukocytes, with 31% lymphocytes, 2% monocytes, 65% neutrophils, and 3% eosinophils. There were 1.1% reticulocytes and 65,000 thrombocytes. The report of the blood smear read, "Platelets markedly reduced, moderate leukopenia, anisocytosis without much polychromasia." The total protein level of the blood was 7.47 mg. per 100 cc. The albumin-globulin ratio was 3.91:3.56. The blood urea level was 106 mg. per 100 cc., creatinine 2 mg., and sulfate 8.2 mg. The sedimentation rate was 131 mm. per hour (Westergren). There was no bilirubin on the direct test, but the indirect test revealed 1.4 mg. per 100 cc. of serum. Serologic tests for syphilis were negative. The lupus erythematosus test was negative.

Cystoscopy revealed "moderate urethritis and cystitis cystica over the base." A chest roentgenogram revealed no abnormali-ties. A gastric roentgenogram showed a "hiatal hernia with about one-third of the stomach above the diaphragm." Bone marrow (sternal aspiration) on volumetric study yielded 3% fat, 67% plasma a myeloid-erythroid layer of 1% and 29% erythro-cytes. Examination of bone marrow smears revealed "a hypo-cellular marrow with lymphocytes being the predominating cell. There are a few granulocytes present, only an occasional normoblast seen and no megakaryocytes found." Fixed tissue sections of the marrow disclosed aplasia of the bone marrow, with replacement by fatty tissue.

The patient's course in the hospital for 22 days was relatively quiet, since she had neither active hemorrhage nor agranulocytic complications. The anemia, however, was troublesome. The concentration of hemoglobin fell from 11.3 gm. to 9.7 gm. to 8.8 gm. per 100 cc., on a weekly basis, while the reticulocytes ranged between 1% and 1.5%. Three blood transfusions, of 500 cc. each, were administered and the concentration of hemoglobin was 13.4 gm. per 100 cc. of blood at the time of dismissal. Cortisone was administered for two weeks without any evidence of benefit, and the woman was returned to the care of her family physician, who was to give transfusions as indicated. Four weeks after her return home she had continued on the same course, requiring transfusions to combat her anemia but otherwise doing well.

CASE 9.—In 1926, this white woman had received a diagnosis of chronic, discoid lupus erythematosus. She had been given multiple treatment, including quinine, ultraviolet light and colloidal gold. To the last of these she had reacted unfavorably. In the autumn of the year in which the diagnosis had been made, she came to the Mayo Clinic, where she spent 58 days in a Rochester hospital. On Oct. 19, 1926, results of laboratory work were reported as normal except that evidence of mild hypochromic anemia was found.

On March 12, 1928, because of a flare-up of the lupus erythematosus, the patient was readmitted to the Rochester hospital, where she remained for 49 days. At that time the laboratory findings again were normal except for anemia (the hemoglobin level was 70%). The patient had no other illness until 1934, when the cutaneous lesions of lupus erythematosus flared again. This condition waxed and waned in a mild way until her next admission.

At the time of the admission just mentioned, which was in January, 1946, the woman complained of shifting joint pains of about two months' duration, with associated afternoon fevers and night sweats. The joint pains were severe enough to keep the patient in bed. There was also a history of recurring urinary infection. It was believed at this time that she had "chronic discoid lupus erythematosus with arthritis." There was evidence of pyuria. Esch. coli were cultured from the urine and sulfathiazole, 7½ grains (0.482 gm.), was given three times a day. All symptoms improved, with clearing of the urinary infection. The patient spent 110 days in the hospital on this occasion, during which time she was given, in addition to the treatment mentioned, bismuth arsphenamine sulfonate (bismarsen®) and quinine. She received, also, two transfusions of blood of 250 cc. each.

Results of laboratory work at the time of her admission in 1946 were reported as follows:

The urine contained albumin, grade 2, pus, grade 2, and Esch. coli on culture. The hemoglobin level was 10.2 gm. per 100 cc. There were 3,250,000 erythrocytes per cubic millimeter and 5,900 leukocytes, with 33% lymphocytes, 11% monocytes, 54% neutrophils, 1% eosinophils and 1% basophils. The blood smear showed a "toxic picture." Serologic tests for syphilis were negative. A chest roentgenogram revealed no abnormality. Roentgenograms of the joints showed "rheumatoid arthritis involving most of the joints examined." The sedimentation rate was 126 mm. per hour (Westergren). The serum protein level was 6.1 mg. per 100 cc. The albumin-globulin ratio was 1.4:1 mg. per 100 cc. At the time of the woman's dismissal, there were no abnormal laboratory findings other than mild elevation of her sedimentation rate.

In 1948, at the age of 60 years, she went to her local physician because of urinary frequency and, on pelvic examination, an early squamous cell epithelioma, grade 2, of the uterine cervix, was found and was cauterized. She was then referred to the Mayo Clinic for further advice and treatment. Pelvic examination at the clinic gave no evidence of extension; consequently, treatment for the carcinoma was limited to a course of roentgen rays. Examination in the section of dermatology revealed "mild lesions of chronic discoid lupus erythematosus, with no systemic reflections." Results of general examination otherwise were not remarkable. The patient had had no trouble with the arthritis in the two years since she had been at the clinic, but she had had recurring urinary infection, which had become more frequent and troublesome. Streptococcus faecalis was found in the urine. Therefore, calcium mandelate was administered and acidification of the urine was effected. Laboratory studies at this time revealed that leukocytes numbered 4,500, of which 50% were neutrophils. All other values were within normal range.

In January, 1949, the patient returned to have her pelvis reexamined. She related that she had had another attack of cystitis, which had persisted for 34 days before responding to treatment. On examination there was no evidence of local recurrence of the cervical carcinoma. No other examinations or laboratory procedures were carried out at that time.

In June, 1949, reexamination of the pelvis gave no evidence of recurrence of the carcinoma and the remainder of the physical examination also indicated that the patient's condition was satisfactory. An attack of cystitis again had occurred in May, 1949, and had been treated with a total of 9 gm. of aureomycin. There was still some evidence of urinary frequency and the "lupus erythematosus was the same." Laboratory examinations at this time disclosed nothing abnormal except pyuria. Results of cystoscopic examination were reported as follows: "Bladder capacity reduced. Moderate, subacute, diffuse cystitis and dilated vessels. Factitial cystitis." Local treatment for 10 days consisted of the use of suppositories of strong silver protein and instillations of 5% mild silver protein. Aureomycin was administered for five days. Much symptomatic improvement was brought about and the urine returned to normal.

Reexamination in November, 1949, gave no evidence of recurrence of the cervical carcinoma. The lupus erythematosus was the same, and the patient was having very little trouble with the cystitis. Laboratory studies again yielded values within normal limits. The patient returned again, in May, 1950, for her usual six months' reexamination, and no evidence was found of recurrence of the carcinoma. The discoid lupus-erythematosus was unchanged. "A severe anemia" was found and the woman was referred to the medical section for further study. The following history was obtained:

During the last month the patient had noticed excessive fatigue as well as exertional dyspnea. She had had mild epistaxis without any previous experience of such trouble. The patient also noted that she was bruising easily and ecchymotic areas appeared spontaneously on the limbs and other parts of the body. It developed that her urinary distress had recurred and that she had been given chloramphenicol; in fact, she had been taking 1 capsule of the drug (250 mg.) every night at bedtime for the last six months. The history and results of physical examination otherwise were not remarkable. Laboratory survey revealed the following:

The hemoglobin level was 11.0 gm. per 100 cc. There were 2,960,000 erythrocytes and 4,200 leukocytes, with 62.5% lymphocytes, 3.5% monocytes, 32.5% neutrophils, 0.5% eosinophils, and 1% basophils. There were 1.1% reticulocytes and 37,000 thrombocytes. The sedimentation rate was 56 mm. per hour (Westergren). The blood urea level was 28 mg. per 100 cc. There was no serum bilirubin on the direct test, and 1.2 mg. on the indirect test. Serologic tests for syphilis were negative. A blood smear revealed anisocytosis, with scattered macrocytes, some polychromasia, neutropenia, and diminished number of thrombocytes.

There was no dye retention on a sulfobromophthalein test of liver function. Analysis of gastric content showed 56 degrees of total acidity and 36 degrees of free hydrochloric acid in a quantity of 125 cc. A roentgenogram of gallbladder revealed cholelithiasis. A roentgenogram of stomach revealed no abnormalities. Volumetric study of bone marrow material aspirated from the sternum revealed 13% fat, 57% plasma, 1% myeloid-erythroid layer, and 29% blood cells. Examination of smears of marrow revealed a "hypoplastic marrow." Results of examination of fixed tissue preparations of the marrow were reported thus: "structure of a hypoplastic marrow."

Following withdrawal of chloramphenicol, the cystitis immediately flared up but local treatment with 5% mild silver protein, with tampons of strong silver protein and procaine penicillin gave relief. Treatment recommended for the hematological condition consisted of a high protein, high vitamin diet, with intramuscular injection of 15 mg. of vitamin B_{12} twice a week.

The patient's home physician supplied the follow-up data. It is now two years since we last observed her. Following her return home, hematinics and vitamin supplements were used and all other drugs were withdrawn. Treatment with cortisone was carried on for about two months, and then was discontinued for lack of evidence of benefit. No episodes of acute bleeding occurred, however, and as the months passed, the blood values slowly returned to normal.

In July, 1951, the following values were reported:

There were 4,100,000 erythrocytes and 6,000 leukocytes, with 55% lymphocytes. There were 90,000 to 160,000 thrombocytes.

In May, 1952, the following data were reported: The hemoglobin level was 12 gm. per 100 cc. The erythrocyte count was 4,700,000 and the leukocyte count 4,000 to 6,000. There were 238,000 thrombocytes. The differential leukocyte count revealed 50 to 60% lymphocytes, and 40 to 45% neutrophils. The patient has not received chloramphenicol since 1950.

Case 10.—A white woman, 18 years of age, was admitted to the Mayo Clinic on May 8, 1952, because of severe and persistent anemia, which had necessitated repeated blood transfusions. She had had what she called "chronic sinusitis," the evidence for which seemed to consist primarily of a postnasal drip. Because of this, she had been given chloramphenicol on Dec. 11, 1950. The prescription had called for 16 capsules, and she had had the prescription refilled until, by July, 1951, she had taken about 60 capsules. By the time she had taken that many capsules, she had begun to notice that she bruised easily but, she stated, she had been rather listless and tired since April, 1951. In August, 1951, she had noticed ecchymosis in areas of slight trauma and had visited her physician. Repeated studies of the blood at that time were reported to have given evidence of a satisfactory condition. For example, the hemoglobin level was 11.35 gm. per 100 cc. There were 4,180,000 erythrocytes and 5,700 leukocytes, with 38% lymphocytes, 60% neutrophils, and 2% eosinophils. There were 317,000 thrombocytes.

Two months later (November, 1951), the ecchymotic areas still had been recurring and laboratory work had revealed slight decrease in all blood values: The hemoglobin level was then 65%. There were 3,370,000 erythrocytes, 3,800 leukocytes, and 200,000 thrombocytes.

In December, 1951, petechiae had appeared for the first time and again she had consulted her physician. At this time the blood thrombocytes had decreased to 50,000 per cubic millimeter of blood while the other blood values were about the same. The hemoglobin level was 9.3 gm. per 100 cc. The erythrocyte count was 3,450,000 and the leukocyte count 3,600, with 59% lymphocytes, 3% monocytes, and 38% neutrophils. Studies of bone marrow were made at this time, and the report indicated the presence of "hypoplastic bone marrow."

In January, 1952, reexamination of the blood yielded essentially the same results as before, except that the blood thrombocytes had decreased to 21,000. Examination of the blood in February, 1952, revealed a hemoglobin level of 8.4 gm. per 100 cc. There were 3,070,000 erythrocytes per cubic millimeter and 1,900 leukocytes with 68% lymphocytes, and 32% neutrophils. At the time of this examination the hematologist reported that some of the lymphocytes were atypical. Corticotropin was given for three weeks without noticeable improvement in the blood picture, and then its administration was discontinued.

The laboratory survey in April, 1952, resulted in the following data: The hemoglobin value was 9.4 gm. per 100 cc. There were 3,450,000 erythrocytes, and 2,800 leukocytes with 70% lymphocytes, 27% neutrophils, 2% eosinophils, and 1% basophils. There were 28,000 thrombocytes.

At this time the patient had had a massive gastrointestinal hemorrhage, with syncope, requiring hospitalization and two transfusions of blood. After that time (March, 1952), she had received a transfusion of blood every two weeks to combat her anemia. Cortisone also had been given intramuscularly three times a day for seven days, but with questionable benefit. At the time of the patient's admission to the Mayo Clinic, she was pale and her blood pressure was 80 mm. Hg systolic and 50 diastolic. Her temperature was 99 F. Scattered ecchymotic areas and multiple petechiae were noted over the lower extremities.

Results of laboratory work on this occasion were reported as follows: The urine was normal. The hemoglobin level was 7.9 gm. per 100 cc. There were 2,470,000 erythrocytes per cubic millimeter and 2,600 leukocytes, with 65% lymphocytes, 9% monocytes, 25% neutrophils, and 1% eosinophils. There were 1.3% reticulocytes and 80,000 thrombocytes. The bleeding time was 17 minutes.

The report of the blood smear read "Anisocytosis with some macrocytosis, polychromasia and basophilic stippling. Platelets are reduced. Leukopenia with relative lymphocytosis. No remarkable immaturity was evident." (One normoblast was seen.) Serologic test for syphilis was negative. A Coombs' test was negative. The serum bilirubin level by the indirect test was 0.7 mg. per 100 cc., and negative by the direct test. The prothrombin time was 19 seconds. Volumetric study of aspirated bone marrow yielded a myeloid-erythroid layer of 2%, while examination of the bone marrow smear revealed "a hypoplastic marrow with decrease in the myeloid line and only a rare immature megakaryocyte seen. The normoblastic line is abnormal in that the cells are suggestive of megaloblastic changes, many with fragmentation and karyorrhexis of nuclei. These abnormal appearing erythroid elements show much mitotic activity. Fixed preparations show little nests of these cells with many mitotic figures. Plasma cells are numerous and the fixed tissue sections show a fatty, hypoplastic structure."

A study of bone marrow on the day of dismissal, May 19, 1952, revealed a myeloid-erythroid layer of less than 1%, while examination of the bone marrow smear preparations showed, "The erythroid line is about as before while the myeloid line is depressed. There is an increase in mature lymphocytes and plasmacytes. Only one megakaryocyte could be found." The patient was returned to the care of her home physician, who has continued to administer cortisone in therapeutic doses and to give transfusions of blood as her anemia dictates. Three weeks after her dismissal from our care, her condition continued to follow the same course.

POSSIBLE MECHANISM, RAPIDITY OF EFFECTS, AND INEFFECTIVENESS OF TREATMENT

In analyzing the foregoing reports, there seem to be at least three patterns. One of these suggests a sensitivity mechanism. In four cases (cases 1, 2, 6, and 7) the initial course of treatment with chloramphenicol seemed to be unattended by ill effects, whereas the second course seemed to precipitate the failure of bone marrow. In two of these four cases (cases 1 and 2) also, there were immediate drug reactions of nausea and vomiting, followed by jaundice in case 2. Three cases in which treatment was intermittent (cases 3, 8, and 10) may well fit into the same pattern, but it was impossible to obtain a history whereby ingestion of the drug and appearance of signs and symptoms of aplastic anemia could be exactly related in time. It is worthy of note that only four capsules of the drug constituted a second course in two cases (cases 2 and 6).

Acute aplasia of bone marrow was precipitated in two cases (cases 4 and 5) by a single course of chloramphenicol. However, gradual suppression of the bone marrow may be a third mechanism. In case 9 such suppression followed daily ingestion of 1 capsule of chloramphenicol for six months and recovery eventually resulted after withdrawal of the drug. Some of the cases (especially case 8) in which treatment with chloramphenicol was intermittent, might actually belong to this group.

There was a history of previous sensitivity to penicillin in two cases (cases 2 and 7), a history of reaction to gold in case 9, a history of hay fever in case 1, and a history of vasomotor rhinitis in case 10. Perhaps, in these cases, allergic diathesis existed. Such a history should be considered important when therapeutic agents must be chosen.

It is not possible to tell from these cases whether careful hematological examinations of the patients who were receiving the drug would have forestalled the tragic complication but we think not. The dosage of the drug for most of the patients who died was figured in hours rather than in days or weeks. In most cases purpura appeared about four weeks after the beginning of the precipitating course of treatment. All fatalities were attributable to uncontrolled hemorrhage.

No treatment has been of avail in these cases. It seems that cortisone, corticotropin (ACTH), and vitamin B_{12} have had fair trials without obvious effect. Had the cases not terminated fatally in such a short time, more satisfactory evaluation of such treatment might have been possible. Repeated transfusions are indicated for supportive treatment.

ADDENDUM

Two more patients who have aplastic anemia associated with ingestion of chloramphenicol have been admitted to our hospital service since this paper was submitted for publication. Both patients are men of middle age, and the purpuric manifestations, anemia and findings relative to the peripheral blood and bone marrow are similar to those of the patients whose cases have been reported here. One man initially took only 4 capsules of the drug in treatment for a sore throat. He repeated the dose both one and two months later; thus, he took a total of 12 capsules. The other man intermittently took capsules for nine months, in treatment of a chronic infection of the urinary tract, until he had taken 160 to 180 such capsules. The bone marrow of the latter patient contained distinctly more normal cellular elements than that of the former one.

Treatment of Prostatic Cancer.—Hormonal therapy is at present the treatment of choice for the great majority of patients suffering from prostatic cancer. Remarkable relief of symptoms with regression of the local lesion and of metastases has been observed in about three-fourths of the treated cases. Many, however, soon relapse.

Statistics now indicate some increase in the ultimate survival time of patients treated by castration and estrogens. The latter are usually first used in the still localized cases without metastases, reserving orchiectomy for the patients who do not respond or in the event of a later recrudescence.

Advanced carcinoma with metastases is treated by orchiectomy combined with estrogen therapy. Experiments with bilateral total adrenalectomy in the treatment of relapsed prostatic carcinoma await the judgment of time.

The only reported cures, however, have been effected by radical surgery. Nevertheless, the over-all prognosis is discouraging, since radical prostatectomy is applicable only to a small fraction of the total number of cases. This low percentage of operability is due mostly to the advanced nature of the lesion when first detected, as well as to the age and the debilitated condition of some of the patients. Effort should be made toward early diagnosis by means of periodic rectal examination. There is doubt, however, as to whether all the small so-called "occult carcinomas" accidentally discovered and cured by radical prostatectomy are indeed biologically malignant.

Preoperative hormonal therapy may render more patients amenable to radical surgery and may thus in the future lead to a higher rate of curability.—Seymour F. Wilhelm, M.D., Carcinoma of the Prostate, *The Medical Clinics of North America*, May, 1952.

CHLORAMPHENICOL AND APLASTIC ANEMIA

Jack J. Rheingold, M.D.
and
Carroll L. Spurling, M.D., Washington, D. C.

Since chloramphenicol is an efficient broad spectrum antibiotic that is widely used, the possibility that it may be the cause of hematological disorders is, naturally, a serious one. Recently, five cases of fatal aplastic anemia have come to our attention. In each instance, we believe chloramphenicol to be etiologically implicated. It is our purpose to report these cases and to review the literature on hematological disorders believed to be caused by this drug.

REPORT OF CASES

CASE 1.—A 31-year-old housewife had received phenobarbital and atropine intermittently for over a year because of nervousness. In December, 1951, an upper respiratory tract infection developed, and she was given a total of 15 capsules of chloramphenicol. Early in January, 1952, she received an additional six capsules. On this occasion, urticaria developed over the lower extremities and lasted for several days. No other recent history of exposure to drugs or toxic agents could be obtained, and the allergic history was otherwise negative. About Feb. 1, 1952, she first noticed malaise and lack of energy, and on Feb. 8, petechiae appeared on her arms and legs. She was hospitalized on Feb. 15, and pancytopenia with hypocellular bone marrow was found. The patient was transferred to the Walter Reed Army Hospital on Feb. 26.

On physical examination she appeared to be in no distress, and the only conditions of note were pallor of the skin, scattered petechiae, and several ecchymoses over the arms and legs. Laboratory tests on admission showed 3,250,000 red blood cells per cubic millimeter; hemoglobin, 9.7 gm. per 100 cc.; 3,000 white blood cells per cubic millimeter, with 88% lymphocytes, 9% segmented neutrophils, 2% monocytes, and 1% eosinophils; 0.3% reticulocytes; and 20,000 platelets per cubic millimeter. The bleeding time was 43 minutes and the coagulation time, 4 minutes. A tourniquet test was highly positive. Results of urinalysis were normal, except for a trace of albumin. A roentgenogram of the chest was normal. Two examinations of aspirated bone marrow showed an extremely hypocellular marrow consisting of about 85% adult lymphocytes. The same condition was observed in marrow slides transferred from the hospital in which the patient had been previously.

The patient was given corticotropin (ACTH), 40 mg. daily administered intravenously, and large doses of vitamin B_{12}, ascorbic acid, and vitamin K. Transfusions of freshly drawn blood (using plastic bags) were given as indicated. Because of difficulty with intravenous administration, the corticotropin therapy was stopped after four days, and cortisone, 200 mg. daily given orally in divided doses, was administered. Despite treatment, the patient's course over the next two weeks was gradually downhill. She continued to bleed vaginally after the onset of her regular menstrual period on Feb. 22. Petechiae and ecchymoses became more evident. Nine transfusions in a two week period were required to keep the hemoglobin level at about 10 gm. per 100 cc. Results of blood determinations done on March 11 were 1,900,000 red blood cells; hemoglobin, 7.4 gm. per 100 cc.; 1,450 white blood cells, with 95% lymphocytes; 0.2% reticulocytes; and 4,700 platelets. In the evening of the same day, the patient complained of abdominal distention, and within an hour the blood pressure had dropped to a shock level. Despite administration of 10 units of blood during the next 24 hours, the patient remained in shock and died on March 15, after having a short convulsive seizure.

At autopsy, numerous petechial and ecchymotic lesions scattered over the body were seen. The peritoneal cavity contained about 800 cc. of fresh blood. There was a large hematoma of the left ovary, obscuring most of the ovarian tissue. On microscopic section, the blood was seen to be coming from a hemorrhagic corpus luteum. Petechial hemorrhages were scattered throughout the white matter of the brain, the heart, gastrointestinal tract, and kidneys. The bone marrow grossly appeared pale brown and on section showed marked hypocellularity, with small foci of cells, which were mainly lymphocytes, seen only occasionally. Small foci of extramedullary hematopoiesis were seen in the abdominal lymph nodes, liver, and spleen.

Comment.—This was a 31-year-old housewife who took a total of about 5.5 gm. of chloramphenicol in two courses and in whom fatal aplastic anemia developed three to four weeks later. It is of interest that urticaria lasting several days developed when the second course was administered. The patient had had no other drugs known to cause aplastic anemia within a reasonable period prior to her fatal disorder.

CASE 2.—A 23-year-old man gave a history of having had recurrent sinusitis over a period of several years. For the first time, in November, 1951, he took 24 capsules of chloramphenicol because of an upper respiratory tract infection and sinusitis, and he took the same number again in early December. At the same time he took APC (aspirin, acetophenetidin, and caffeine) tablets, codeine, phenylephrine (neo-synephrine®) hydrochloride nose drops, and "black-colored nose drops." On Dec. 10, 1951, scattered petechiae and ecchymoses developed. Over the next two months, he noticed increasing weakness and dull frontal headaches. On Feb. 6, 1952, he had a mild epistaxis and was admitted to another hospital. Extensive studies done at that time showed pancytopenia and extremely hypocellular bone marrow on repeated aspiration. The patient stated that during this hospitalization he again received about 24 capsules of chloramphenicol because of a small ulcer on his lip. Other medication at that time consisted of analgesics for headache and ascorbic acid. Although the patient had worked in an army hospital pharmacy for 11 months previously, he denied taking any other drugs. The allergic history was negative.

On admission to Walter Reed Army Hospital, physical examination showed a fair degree of pallor and scattered petechiae over the trunk and lower extremities. Laboratory data were as follows: 1,800,000 red blood cells per cubic millimeter; hemoglobin, 6.2 gm. per 100 cc.; 1,800 white blood cells per cubic millimeter, with 10% segmented neutrophils and 89% lymphocytes; 7,500 platelets per cubic millimeter; 0.2% reticulocytes; and a hematocrit of 20%. The bleeding time was more than 16 minutes, and the clotting time was 5 minutes. A tourniquet test was highly positive. Roentgenograms of the chest, sinuses, mastoids, and abdomen were normal. Urinalysis showed many red blood cells and a few white blood cells per high power field. Aspiration of sternal marrow showed it to be extremely hypocellular, with 90% adult lymphocytes.

The patient was given cortisone, 300 mg. per day administered orally in divided dosage, vitamin B_{12}, ascorbic acid, and fresh blood transfusions as indicated. He was given penicillin, aureomycin, or terramycin during most of his hospital stay. Ten pints of blood were required to maintain the hemoglobin level at about 10 gm. per 100 cc. Gastrointestinal bleeding, high fever, jaundice, and pneumonitis developed terminally, and the patient died on May 4, 1952.

At autopsy, the skin of the entire body was moderately icteric and covered with petechiae and ecchymoses. Scattered throughout the myocardium, lungs, liver, spleen, and kidneys were large numbers of round soft white nodular areas 4 to 5 mm. in diameter. The entire gastrointestinal tract, from stomach to anus, showed myriads of similar mucosal nodules with ulcerated punched out centers. On microscopic section, these areas were observed to be large colonies of bacteria and fungi, which on culture were found to be hemolytic Staphylococcus aureus and Candida. Surrounding the colonies there was practically no in-

---

flammatory reaction, although some necrosis was present, particularly in the liver. The lungs showed, in addition, diffuse hemorrhage and hemorrhagic infarction. There was a diffuse organizing pneumonitis. The bone marrow grossly appeared light tan in color; on section there was moderate hypoplasia, with virtual absence of granulocytic elements and megakaryocytes. The cells consisted mainly of lymphocytes and plasma cells, with a few nucleated red blood cells. Foci of extramedullary hematopoiesis were found in the liver, lymph nodes, and spleen. The spleen also showed considerable erythrophagocytosis.

Comment.—This was a 23-year-old soldier who had taken three courses of chloramphenicol for a total dose of about 18 gm. The aplastic anemia became apparent about one week after the second course, and a third course was taken during the aplastic process. Despite therapy, he died about 145 days after onset.

CASE 3.—Furuncles developed in an 18-year-old college student in the late summer of 1951. She said she had been given chloramphenicol in August, 1 capsule every 3 hours while awake for 2 weeks. The records of her physician showed that she had received a short course in June and another in July for furunculosis, with no record of any drug being taken in August. In early October, the patient first began to notice scattered ecchymoses, which continued to recur. Late in October, she had an upper respiratory tract infection and took two more capsules of chloramphenicol without the physician's advice. In late November, she first began to notice petechiae. Blood studies on Nov. 21, 1951, showed 3,800,000 red blood cells per cubic millimeter; hemoglobin, 11.6 gm. per 100 cc.; 5,100 white blood cells per cubic millimeter with 37% segmented forms, 6% band forms, 56% lymphocytes, and 1% monocytes. The platelet count was 34,200 per cubic millimeter. The patient had another furuncle about this time, which responded to hot soaks and ammonium ichthyolsulfonate ("icthyol") ointment. Pallor, fatigability, and dizziness had been noticed about this time. The patient was admitted to the George Washington University Hospital on Dec. 8, 1951. Physical examination at that time revealed mild pallor, crops of petechiae, ecchymoses, and several mucous membrane hemorrhages in the mouth. Laboratory data revealed 9.7 gm. of hemoglobin per 100 cc., 2,700,000 red blood cells, and a hematocrit of 25%. The platelet count was 27,000, and the white blood cell count was 6,000, with 50% segmented neutrophils, 49% lymphocytes, and 1% monocytes. The bone marrow aspirated from the sternum had a fair number of cells with no megakaryocytes. Macronormoblasts were seen, and there was some increase in adult lymphocytes and plasma cells. The result of the van den Bergh test was normal, and that of Coombs' test was negative. There was no response to vitamin B_{12}, liver extract, or folic acid therapy, which was tried because of the macronormoblasts. Bone marrow aspiration repeated a week later showed a definite decrease in the number of cells and a further increase in the percentage of lymphocytes and plasma cells. The patient was started on corticotropin therapy, which later was changed to cortisone therapy, 200 mg. per day administered orally in divided doses, for ease of administration. From this time until her death on Feb. 27, 1951, a progressive aplastic anemia gradually developed, which was characterized by anemia, thrombopenia, leukopenia, and an aplastic bone marrow. Therapy was continued with large doses of cortisone (100 to 300 mg. per day given orally) throughout this time. The only apparent effect of this drug seemed to be suppression of bleeding, at least until the terminal complication. The bone marrow showed complete aplasia, with only lymphocytes and plasma cells remaining. Other treatment included testosterone, thyroid, vitamin B_{12}, folic acid, liver extract, and repeated transfusions as indicated. Five cubic centimeters of normal marrow injected into the patient's sternal cavity resulted in only a severe febrile reaction. Her course was marked by occasional furunculosis in the axillae, which responded to large doses of penicillin. Bleeding occurred into the skin and mucous membranes and on one occasion from the kidneys for three days. In early February, the patient had severe epigastric pain and several days later passed liquid reddish and black stools. Her final episode was an overwhelming melena that persisted for three days, with marked abdominal distention, and she finally died, despite continuous transfusions.

Comment.—This 18-year-old girl took chloramphenicol for recurrent furunculosis, and about five weeks later purpura developed. Over the succeeding months an aplastic anemia developed, and she finally died of overwhelming gastrointestinal bleeding. She had taken no other drugs previously. It is a point of issue whether the patient took additional chloramphenicol on her own initiative in August or whether the drug administered in July was the last she took prior to the development of symptoms of thrombopenia in early October.

CASE 4.—A 36-year-old white waitress was first admitted to the George Washington University Hospital on July 21, 1951, for treatment of an indolent ulcer on the medial aspect of her right ankle. This had developed several years previously following an injury and had resisted treatment since that time. Blood determinations at this admission were hemoglobin, 13.9 gm. per 100 cc.; hematocrit 46%; and leukocytes 10,450 per cubic millimeter; with 68% segmented neutrophils and 32% lymphocytes. The ulcer base cleared following aluminum acetate (Burow's) solution soaks, and granulation and healing finally occurred. During the patient's stay, a serologic test for syphilis was found to be positive. She received the following therapy: chloramphenicol, 500 mg. every 6 hours for 2 days, then 250 mg. every 4 hours for 26 days, and finally 500 mg. every 6 hours for 8 days, for a total of 61 gm.; sulfisoxazole (gantrisin®), 1 gm. every 4 hours for 9 days, for a total of 54 gm. (discontinued July 9, 1951); in addition, she received aluminum acetate solution compresses; pentamethonium chloride; phenylephrine hydrochloride nose drops; aureomycin "pharyngets," 1 every 2 hours from July 25, 1951, to Aug. 7, 1951; "vi-syneral" (a multiple vitamin preparation), intramuscularly administered; dihydrocodeinone (hycodan®) bitartrate, and lyocyte® (dried red blood cell concentrate) powder applied to the ulcer crater.

The patient was readmitted on Nov. 23, 1951, saying that she had continued taking chloromycetin for another three weeks (dosage unknown) following her discharge from the hospital. She also had had a short course of priscoline® (2-benzyl-2-imidazoline hydrochloride), which was discontinued because of gastrointestinal intolerance. She had last taken chloramphenicol near the middle of September. About 10 days before admission, she first noted petechiae and ecchymoses. Ulorrhea began three days before her admission to the hospital. Examination revealed an acutely ill woman with a temperature of 39.4 C (102 F). Petechiae were scattered over all the extremities, the face, and the trunk, and ecchymoses were noted on the thighs and arms. The gums were spongy, with a few small areas of necrosis. Blood determinations at that time showed 12.4 gm. of hemoglobin per 100 cc.; hematocrit of 40%, 4,300,000 red blood cells, 1,900 white blood cells, with 20% segmented neutrophils, 4% band forms, and 76% lymphocytes. Sternal puncture (and later rib puncture) revealed an extremely hypoplastic marrow infiltrated or replaced by lymphocytes and plasma cells. The platelet count was 24,720, and the bleeding time was 15 minutes. There was only slight clot retraction in 24 hours. The clotting time (3 tube Lee and White) was 15 minutes. The patient was started on terramycin and cortisone therapy. Cortisone therapy was discontinued after 11 days, because a high spiking fever developed, and it was believed a bacteremia was being masked. This was borne out by a positive blood culture of a hemolytic Staph. aureus. The patient was given large doses of terramycin, streptomycin, and penicillin. Despite antibiotic therapy, the patient's condition became increasingly toxic. Her red blood cell count, hemoglobin level, and hematocrit gradually fell, despite repeated transfusions, reaching the following low points: 7.3 gm. of hemoglobin per 100 cc., 2,550,000 red blood cells, and a hematocrit of 24%. Her white blood cell count had increased from 1,900 on admission to 7,200 during her hospital course, but the lymphocyte count remained high, and at the time of her death her white blood cell count had dropped to 950. Cellulitis of one arm, severe generalized muscular aching, bilateral chest rales, and abdominal distention developed, and the patient died, having the clinical picture of extreme toxemia.

Comment.—This was a 36-year-old woman with a chronic ankle ulcer who had a positive reaction to a syphilis test and was treated with chloramphenicol and a number of other agents. About two months after she received chloramphenicol, an aplastic anemia became apparent. About four months prior to the onset of the aplastic process, she had received sulfisoxazole and a variety of other medicaments, including aureomycin "pharyngets" (last given three and one-half months before the onset). She had evidence of thrombopenia, leukopenia, and anemia, and died as the result of an overwhelming Staphylococcus bacteremia and toxemia. This case points up the difficulty of establishing an etiological agent, since so many medicaments had been used; however, chloramphenicol was the last agent used before her admission to the hospital, and it had been taken one and one-half to two months after any of the others.

CASE 5.—A 26-year-old white woman had had eczema and acne on her extremities and face for about two years. Her most recent treatment had consisted of chloramphenicol, four 250 mg. capsules taken daily for about two months. This was discontinued on May 18, 1952, because of nausea. On May 2, during therapy, blood tests showed a hemoglobin level of 90% and 8,950 white blood cells, with 72% segmented neutrophils. The patient felt well until about June 10, when profuse vaginal bleeding developed with the onset of her menses. She continued to have hypermenorrhea and was admitted to another hospital on June 16. She said she had had fever for several days, a sore throat, and swollen glands in her neck. She had not taken chloramphenicol previously and had a negative allergic history. She had taken no other drug in the three months preceding the onset of symptoms, except for two butabarbital (butisol®) sodium tablets the day her menses began. She had taken this drug prior to the use of chloramphenicol in an undetermined amount.

Physical examination revealed a young woman who did not appear ill. There was mild bilateral cervical adenopathy, a small amount of whitish exudate on the tonsils, and a small ecchymosis on the posterior pharynx. Her temperature was 100 F, and it varied from 100 to 103 F during her stay at this hospital. Initial blood studies revealed 1,690,000 red blood cells per cubic millimeter, 5 gm. of hemoglobin per 100 cc., 3,300 white blood cells per cubic millimeter, with 50% segmented neutrophils, 46% lymphocytes, 1% monocytes, and 3% eosinophils. The platelet count was 12,500 per cubic millimeter. Petechiae on the extremities and ecchymoses at the site of needle puncture developed during this hospitalization. The patient was given three pints of whole blood, and penicillin therapy in large doses was started. She was transferred to Walter Reed Army Hospital on June 21, 1952.

Physical examination revealed several furuncles in the left axilla, scattered petechiae on the mucous membranes and extremities, a few ecchymoses, and no enlargement of the lymph nodes, liver, or spleen. Laboratory examination revealed 3,900,000 red blood cells, 12.4 gm. of hemoglobin per 100 cc., and 400 white blood cells, with 6% segmented neutrophils and 94% lymphocytes. There were 12,000 platelets. Urinalysis showed nothing remarkable except for numerous epithelial cells. Marrow obtained by sternal puncture was extremely hypocellular, the great majority of cells being adult lymphocytes, with a few plasma cells and, rarely, normoblasts and granulocytes; no megakaryocytes were seen. The diagnosis of aplastic anemia was made.

The patient was continued on penicillin therapy with large doses. It is our intention to begin administering cortisone when her infection has been controlled. Transfusions will be used as indicated.

Comment.—This is a 26-year-old woman who took 1 gm. of chloramphenicol daily for two months for treatment of acne and eczema. Twenty three days after stopping use of the drug because of nausea, menorrhagia began. The diagnosis of aplastic anemia was made because of a pancytopenia and an extremely hypoplastic bone marrow. Her course is unknown since her condition was only recently diagnosed.

COMMENT

Four other cases of aplastic anemia believed caused by chloramphenicol have been reported. It is our understanding that reports of other cases are being readied for publication. Rich and his co-workers [1] reported the case of a 63-year-old white man who was treated for a urinary infection with chloramphenicol for about 80 days, receiving a total dose of 54 gm. Generalized purpura developed while the patient was under treatment, and shortly thereafter a complete aplastic anemia appeared. The patient died 12 days after the onset of symptoms. There were several times during the course of therapy when administration of the drug was discontinued for several days and then restarted. Loyd [2] reported the death of a 28-year-old woman who had been treated intermittently for a year with chloramphenicol for an Escherichia coli urinary infection. She then received two courses of chloramphenicol about a month apart, the first of 1.75 gm. and the second, 5.75 gm. About one and one-half months later, petechiae developed, and the patient showed evidence of a full-blown aplastic anemia. Autopsy showed widespread hemorrhage and replacement of active bone marrow by fat. Harris and co-workers [3] mention two cases of aplastic anemia in an article describing the use of chloramphenicol in the treatment of 68 patients with bronchiectasis. These cases were reported in detail by Wilson, Harris, and others.[4] In each case, aplastic anemia developed during the prolonged administration of chloramphenicol (26 and 28 weeks, respectively), with total doses of 52 and 56 gm., administered 1 gm. twice weekly. Disturbance in platelet function was first noticed. One of the patients died, while the other, at the time of the report, had a hypoplastic marrow and pancytopenia five months after the onset of the toxic symptoms. Gill [5] reported two patients treated for Salmonella infection with chloramphenicol, 250 mg. given immediately and 100 mg. every 3 hours thereafter. The first patient, who had received 6.85 gm., had a drop in the white blood cell count from 11,000 per cubic millimeter, with 42% segmented neutrophils, to 10,200, with only 9% segmented neutrophils. Administration of the drug was stopped, and five days later the patient had a white blood cell count of 9,400 per cubic millimeter, with 40% segmented neutrophils. Because of this case, the next patient was watched closely; with two days' treatment, the second patient's white blood cell count went from 7,000 per cubic millimeter, with 46% segmented neutrophils, to 5,000, with 23% segmented neutrophils. Chloramphenicol therapy was stopped, and the count rose to the previous level in several days.

Volini and his co-workers [6] reported three patients in whom toxic hematopoietic effects were seen following treatment with chloramphenicol. The first of these was a young Negro boy with typhoid, who had received a total dose of 53 gm. over a period of 18 days. Prior to treatment, his blood cell counts were normal, but after discontinuance of treatment, a red blood cell count of 850,000 per cubic millimeter and a white blood cell

count of 3,200 per cubic millimeter, with 8% segmented neutrophils was found. The bone marrow showed a maturation arrest in the red cell series and a diminution of granulocyte precursors. Twenty days after stopping treatment, the values had returned to normal. Two other cases of leukopenia and neutropenia with bone marrow involvement after chloramphenicol therapy were observed. The conditions reverted to normal after several weeks.

An abstract of a paper by Lindau [7] reveals other interesting data. He gave chloramphenicol for 30 days to eight patients, seven of whom had chronic degenerative diseases. In three of these, there was an arrest of the red blood cell maturation, with an average decrease in the hematocrit of 8.6% and a definite decrease of orthochromatic normoblasts in the marrow. After these conditions returned to normal, the drug was readministered to two of the three affected patients. Again the hematocrit fell and returned to normal after administration of the drug was discontinued. Janbon and Bertrand [8] recently reported anemia complicating the use of chloramphenicol in six patients (four with brucellosis, one with typhoid, and one with tuberculosis). The total doses in these cases were 140, 120, 52, 120, 54, and 21 gm., respectively. In each patient, the red blood cell count fell by about 2 million cells per cubic millimeter during the course of therapy. Four patients responded spontaneously, one responded to vitamin B_{12} and another to folic acid. The authors felt that this anemia was of the deficiency type, with inhibition of the antianemic factor due to the action of the antibiotic on the intestinal flora.

SUMMARY

Five cases of fatal aplastic anemia in patients who had taken chloramphenicol are reported. The chloramphenicol may have been the etiological factor in the development of this disorder. The current literature is reviewed.

ADDENDUM

The patient in case 5 died after this paper was submitted for publication.

RELATION OF HOSPITAL ADMINISTRATORS, NURSING STAFF, AND MEDICAL STAFF

Thomas P. Murdock, M.D., Meriden, Conn.

In 1947 the President of the American Medical Association, Dr. Edward L. Bortz, on the recommendation of the House of Delegates, appointed a committee to study the nursing problem in the United States, with particular reference to the shortage of nurses. The members of the original Committee on Nursing Problems were Drs. Warren Draper, Howard Gray, Leland McKittrick, and Donald Smelzer, with myself as chairman.

I think it is fair to say that at that time the other members of the committee had only a general and not an intimate knowledge of the magnitude of the problem. I know it is more than safe to say that the chairman probably knew less about the nursing problem than any man in America. He was soon to learn far more than he had planned for or gambled on.

The study was an intensive and exhaustive one. During the year, the committee met many times with representatives of the American Nurses Association, the American Hospital Association, the American College of Surgeons, and the American Medical Association. Separate meetings were held with representatives of the various organizations, and finally representatives of all of the organizations met together. In the beginning it was quickly noticeable that there was an air of suspicion on the part of the representatives of each organization toward the representatives of the others. A humorous incident took place at one of the meetings when each group sat around a large table and did not talk to the others. Later, when it was recognized that most of the problems were common to all the groups represented and that each group had an interest, that suspicion was abolished.

Soon after the beginning of the study letters began to come in from physicians and hospital administrators condemning the actions of nurses. The tone of these letters was in general severely critical of the nurses. About this time publicity was given to the study, and then the letters from nurses began to arrive. They in turn were critical of the physicians and hospital administrators and, of course, of the committee. Some of the letters were signed and some were anonymous. There were many that were critical of the committee. In substance, they said that the committee could be better occupied by investigating the shortcomings of the members of the medical profession and leaving the nurses to solve their own problems. In both instances the attitude was due to lack of understanding. Unfortunately, I believe that some such feeling still exists among physicians, administrators, and nurses. I think, however, that it is gradually being dissipated.

In 1948 the committee made its final report to the Trustees of the American Medical Association. In the report the committee recommended that nurses be divided into two classes: (*a*) professional nurses and (*b*) trained practical nurses. The professional class was to be subdivided into college-trained nurses who would serve as educators and hospital-trained nurses who would serve as supervisory personnel. The percentages of the total of all nurses in the groups recommended were as follows: 15% were college-trained nurses, 25% were hospital-

---

Read at the meeting of the Catholic Hospital Association of the United States and Canada in Cleveland, on May 27, 1952.

trained nurses, and 60% were trained practical nurses. The committee also recommended that the hospital training courses for nurses be reduced to two years, and the courses for trained practical nurses to one year.

I think the greatest achievement that came as the result of the study was the ability and willingness of representatives of the three groups involved to sit in the same room around a conference table and calmly and dispassionately discuss their common problems. Prior to the appointment of the American Medical Association Committee, Dr. Hugo Hullerman of the American Hospital Association had recommended the formation of a committee representing administrators, nurses, and physicians to study the problems common to all three groups. An invitation to join this group came to the American Medical Association while the Committee on Nursing Problems was making its study. The members of our committee were unwilling to affiliate with this group until the study was completed. In 1948 the Commission for the Improvement of the Care of the Patient was formed, with six representatives from each organization on the commission. The American Medical Association was one of the member organizations, and the Committee on Nursing Problems became part of the commission. Rules for operation were written and adopted, officers were elected, and the organization became a going concern.

Progress, as was to be expected, was slow in the formative years. Now the organization is one of the very hard-working organizations in medicine in this country. The commission meets twice yearly. The attendance has been excellent, and the discussions and debates have been stimulating.

The problems brought before the commission are many and varied. In the beginning, the problems were chiefly related to nursing. Now the commission studies such problems as those relating to administration, medical care, interns, pathologists, radiologists, and anesthetists. In several states committees of representatives of the three groups have been formed to discuss common problems on the state level.

Few physicians are familiar with the problems of the hospital administrator. Budgetary problems are a common headache of the administrator. The difficult personnel problem is another, personality conflicts are another, and allotment of hours of work and of work on different shifts or weekends or holidays is still another. Occasionally there is a controversy as to whether a problem is administrative or comes within the province of the medical staff.

Physicians in general are not familiar with the intricacies of nursing problems. The nursing school problem is one of the difficult ones. There are also the problems of providing nursing service in the hospital when the students are at class, and maintaining required courses to conform to state laws. The required hours for various courses and the required nursing hours per patient day must be scheduled. Budget problems must be solved, and late notices to the nursing administrator that illness will prevent working that day or evening dealt with. There is also the difficulty of getting the physicians to give lectures or bedside courses and of making physicians understand that these are absolutely necessary in the operation of an accepted nursing school.

In the same way, administrators are unable to know or to understand the problems of the medical staff. Suitable staff rooms for conferences are necessary. There must be adequate equipment for all reasonable procedures. A good library must be provided. Cooperation of the administrator must be secured in the teaching program for interns and residents. Cordial and cooperative personnel must serve in the admitting offices.

Again by the same token the nursing leaders and authorities should attempt to know the problems of the medical staff. Some of these problems are very burdensome and the responsibility is great. After all, the person who is chiefly responsible for the end result that his patient obtains is the physician. It should be determined whether there has been backbiting behind the scenes, whether the nursing leaders have been carelessly evaluating physicians to lay persons, and whether nurses have been making relatives unhappy by criticizing the ability of the attending physician.

Another delicate point is the position of the physician who has courtesy privileges but is not a member of the active staff. His position may be due to unwillingness on his part or nonacceptance of him by the regular staff. Every encouragement should be shown him by the administration and the nursing staff. The medical staff should see that he is invited to attend staff conferences so that his will be a continuing educational program. If the criticism comes from him, cordial relations can frequently be established by kindly actions of the administrator or nursing staff or members of the medical staff. If the criticism comes from the administrator or the nursing staff or the medical staff, he becomes a better physician by attending staff conferences and by being familiarized with the problems of the administrator or the nursing staff.

I feel that, whenever there is disagreement in hospitals between administrators, physicians, and nurses, they are due to lack of understanding of one group of the problems of the other. I am sure that a hospital Committee for the Improvement of the Care of the Patient would help a great deal in understanding and even in solving these problems. We are all too prone to be critical of the other fellow's shortcomings when we do not know or understand his problems. It seems to me that we will not be doing our full duty to the patient until we have set up in each hospital such a committee, bringing this advancement, and I feel it is a real advancement, directly to the patient. This hospital committee made up of representatives of the three groups would go far to aid in the solution of all of these problems. I would recommend also that the representatives be top flight persons from each group.

One of the great problems confronting the American people today is the cost of hospital care. At the turn of the century and as late as the beginning of the second decade of this century, the cost to the patient in a ward was $1 a day, in a semiprivate ward, $1.50 a day, and in a private room, $2 a day. What a sad awakening one has when he receives his hospital bill today. A two weeks' stay in a private room for a surgical patient will cost about $500.

We glibly state that the average patient now becomes ambulatory more quickly and is discharged in about eight days, whereas before he remained in the hospital about 14 days. Obviously this is not the whole answer. Heretofore, it was the common practice of the hospital to furnish all but the most unusual and most expensive medications without charge. There was only limited use of x-rays. Laboratory work was limited and usually insignificant. Anesthetics were administered by an untrained doctor or nurse. Ether and chloroform administered by drops were about the only anesthetics used. All of this has been changed, and necessarily so.

Are we as physicians depending too much on instruments of precision? Are we depending too much on the use of x-rays in chest examinations instead of the careful use of the stethoscope? Are we asking young laboratory technicians to make our diagnoses for us? Are we placing too much reliance on intricate laboratory tests when a careful history and physical examination would give us a more reliable answer? Are we placing too much stress on basal metabolic readings when a careful history of weight gain or loss, heart rate, blood pressure readings, hair distribution, and bodily stature would give us a more reliable answer? Are we leaning too heavily on electrocardiographic tracings when a careful history and physical examination would tell us more? These are some of the questions we must ask ourselves and answer if we are to contribute to the reduction of the cost of efficient hospital care.

How many of us as physicians are familiar with the cost of the antibiotics, sulfonamide drugs, cortisone, or corticotropin (ACTH)? Have we been using these preparations carelessly or without indication? Have we been using two antibiotics that might have antagonistic effect? These also are some of the questions we must ask ourselves and answer if we are to help solve this problem. How many of us are familiar with the cost of anesthesia, blood and blood derivatives, intravenous fluids, physiotherapy, basal metabolic readings, electrocardiograms, and roentgenograms? How many of our patients are being kept in private rooms in a general hospital when they would do as well or perhaps even better in a convalescent home if they are faced with long-term illnesses at great cost to the patient and the hospital?

In the past each department in the hospital has felt that its own department was a separate department and was not the concern of the others. Now we have come to know that all departments are definitely interrelated and that the work of each department must be coordinated with the others if we are to give our patients efficient and economical care.

For a long time, I have felt that a hospital operating too far out of the red was defeating the purposes for which it was intended. When great profits are shown, that profit comes from blood. God did not intend that. At the same time, I don't think it was intended that waste or carelessness should be permitted that would incur great losses. The dangers of socialism and communism are always before us. Both begin where there is want, and are thrown out as sops to a suffering people. Both are grasped for, as a drowning man grasps for a straw, little realizing the price he eventually pays. The socialist and communist uses the cost of medical and hospital care as one of the great reasons for the adoption of this abominable philosophy.

We must find ways and means to see that our patients are given efficient medical and hospital care and that the cost is kept at a reasonable amount. If the present procedures continue, the cost of medical and hospital care will continue to increase, and the law of diminishing returns will take command. I feel that all of these problems and differences can be solved and answered by the generous cooperation of the hospital administrators, nursing staff, and medical staff. This cooperation can be accomplished, I am sure, by the formation of a Committee for the Improvement of the Care of the Patient in each hospital. It is not a new idea, but it is a practical way of helping to solve these problems. With a joint national Commission for the Improvement of the Care of the Patient functioning on the national level and with committees on state level, it naturally follows that the proper place for implementation is on the hospital level.

I would further recommend that this committee meet monthly or bimonthly and that all of the problems of major or minor importance be reviewed and recommendations made for their solution. This committee should be made up of topflight persons. The seniors and leaders in each department should participate. In this way, persons responsible for policy making could speak for their divisions. We could in this way, and probably better than in any other way, familiarize all with the problems of each toward the end of providing the best medical care for all the people.

Finally we should keep before us, always, this fact: When a husband brings his wife to the hospital, a wife brings her husband to the hospital, a father and mother bring their child to the hospital, they are giving to us, for our care the body of a loved one, life's most priceless possession. We must not fail them.

147 W. Main St.

Histoplasmosis.—The highest levels of histoplasmin sensitivity in any region in the world occur in the east-central part of the USA near the junctions of the Missouri, Mississippi, and Ohio rivers, an area in which clinical cases of histoplasmosis have been repeatedly observed. In Canada, histoplasmin sensitivity has been found only in the south-eastern provinces. A somewhat lower prevalence of histoplasmin reactors than in the USA has been reported from certain localities in Mexico, Central America, and South America; the relatively small number of histoplasmosis cases diagnosed in these areas is suggestive but inconclusive evidence of the existence of endemic centres of histoplasmosis.

There appears to be very little histoplasmin sensitivity wher studies have been conducted outside the Americas. Practicall nothing is known concerning sensitivity in Asia, except for tw investigations in India which revealed a negligible number o reactors to histoplasmin. A great many reports covering mo of the European countries have failed to demonstrate any sens tivity areas, although single, isolated cases of histoplasmos have been diagnosed in Austria, Bulgaria, England, the Nethe lands, Portugal, Spain, and Turkey. Several cases have occurr in the Union of South Africa, which appears to be an area low prevalence of histoplasmin sensitivity, but little is kno of the rest of the African continent. Three cases have been o served in Java, but no studies of histoplasmin sensitivity ha yet been reported.—Alessandro Mochi, M.D., and Phyllis Edwards, M.D., Geographical Distribution of Histoplasmo and Histoplasmin Sensitivity, Bulletin of the World Health ganization, Volume 5, No. 3, 1952.

CLINICAL NOTES

EMERGENCY APPENDECTOMY IN A PATIENT RECEIVING ANTICOAGULANTS FOR MYOCARDIAL INFARCTION

Joseph B. Vander Veer, M.D.
Alan P. Parker, M.D.
and
Frank R. Boyer, M.D., Philadelphia

The present widespread use of anticoagulant drugs for treatment and prophylaxis makes it probable that an occasional patient's treatment will be complicated by the necessity for emergency operation. This subject was brought to our attention by the occurrence of acute appendicitis in a patient receiving bishydroxycoumarin (dicumarol®) for acute myocardial infarction. There was no precedent, in our experience, for the handling of such a problem. The following report gives the important details of our management and the results obtained.

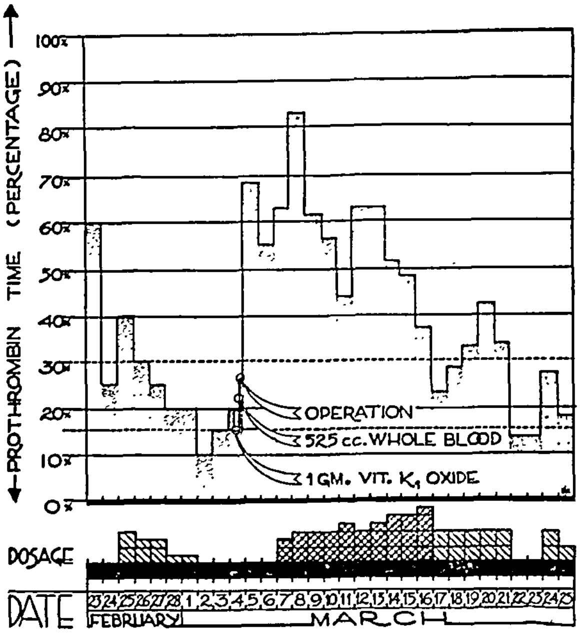
REPORT OF A CASE

T. G., a 47-year-old white man,[1] was admitted to the Coatesville (Pa.) Hospital on the morning of Feb. 19, 1951, with the diagnosis of acute coronary thrombosis. The clinical picture and course were typical, although the electrocardiographic changes were delayed. Anticoagulant therapy, with bishydroxycoumarin, was instituted on the third hospital day. Daily determinations of prothrombin time showed that an effective level of hypoprothrombinemia was maintained during the next 11 days with somewhat less than the average initial daily dosage. Fourteen days after admission, on March 4, the patient experienced diffuse abdominal pain and vomiting with gradual localization of the pain to the right lower quadrant of the abdomen. Definite localized tenderness and rigidity were present, and the diagnosis of acute appendicitis was made by the patient's family physician. After a telephone conversation with one of us (J. B. V.), who had seen the patient on Feb. 26, 1951, as a consulting cardiologist, it was decided to transfer the patient by ambulance to the Bryn Mawr Hospital for observation and possible operation (March 4). A surgical consultant confirmed the diagnosis of acute appendicitis, suspecting local peritoneal irritation, and advised immediate operation.

The prothrombin times on March 1, 2, and 3, were 20%, 10%, and 15% of normal, respectively. On the morning of the day of transfer (March 4) the prothrombin time was 20% of normal. A dose of 50 mg. of bishydroxycoumarin had been given on March 1. Because of the low prothrombin level, no bishydroxycoumarin was given on March 2 or 3. A dose of 50 mg. was scheduled for March 4, but fortunately was withheld because of the abdominal pain. Other medicaments that were given on the day of transfer were meperidine hydrochloride, 100 mg.; streptomycin, 1 gm.; penicillin, 400,000 units; and vitamin K (hykinone®), 20 mg. The last drug was given in two doses of 10 mg. each, intramuscularly, at 4 p. m. and 6 p. m.

It was decided to proceed with laparotomy after rapid preparation of the patient with vitamin K_1 oxide and citrated whole blood and, if unusual bleeding occurred in the abdominal wall, to postpone entering the peritoneal cavity until the bleeding tendency could be corrected. One gram of vitamin K_1 oxide[2] was dissolved in 25 cc. of 95% alcohol, mixed with 500 cc. of isotonic sodium chloride solution, and given fairly rapidly, starting at 9 p. m. This was followed by the administration of 525 cc. of citrated whole blood.[3] Blood for the determination of prothrombin time was taken at 9 p. m., and at 10:30 p. m., frozen overnight, and reported the following day as 15% and 24% of normal, respectively. The operation was begun at 10:45 p. m., with cyclopropane, ether, and oxygen anesthesia after intravenous thiopental sodium induction. Curare (12 mg.) aided in producing adequate relaxation. An acute gangrenous appendix without perforation was found and removed without drainage, the operation being completed at 11:50 p. m. No unusual bleeding was encountered, and no further blood was given.

Recovery from operation was relatively uneventful. The temperature reached 101.6 F within the first 24 hours after operation and gradually fell to normal during the next six days. A mixture of 400,000 units of penicillin and 0.5 gm. of dihydrostreptomycin was given intramuscularly every 12 hours for six days after operation. On the morning after operation the prothrombin time was 68% of normal. On the three following days the prothrombin times were 55%, 63%, and 83% of normal, respectively. Anticoagulant therapy was resumed on the third morning after operation, with ethyl biscoumacetate (tromexan® ethyl acetate). Despite the use of large (single) daily doses of this drug, the prothrombin time did not fall to an effective anticoagulant level during the next 10 days (see the accompanying figure). When bishydroxycoumarin was substituted, it was found that doses much larger than average were needed to produce effective prothrombin levels. This seems significant in view of the less than average doses of this same drug needed to produce the same levels preoperatively.



Serum prothrombin time (percentage) in patient T. G., before and after operation. Each square of diagonal lines indicates 50 mg. of bishydroxycoumarin. Each cross hatched square indicates 300 mg. of ethyl biscoumacetate. The broken lines mark the therapeutic anticoagulant zone.

COMMENT

The problem of surgery in a patient receiving full anticoagulant (bishydroxycoumarin) therapy (prothrombin time, 15% to 20% of normal) was handled empirically and without the benefit of immediate prothrombin time determinations. The good results obtained may have been at least partially due to the fact the patient had had no anticoagulant drug for three days prior to operation. Nevertheless, it would seem that the vitamin K (synthetic), Vitamin K_1 oxide, and citrated whole blood, which were given just prior to surgery, were effective in preventing any abnormal bleeding. The relative efficacy

---

[1] Dr. Julius Margolis provided the data for this patient and gave permission to publish the report.

[2] The vitamin K_1 oxide used was furnished by Merck & Company, Inc., Rahway, N. J.

[3] The blood was obtained from the hospital blood bank and was approximately 48 hours old.

of these different substances cannot be determined in this instance. Our previous experience leads us to believe that the use of the vitamin K_1 oxide was probably an effective measure. The fact that citrated whole blood was given just before the operation must not be overlooked, however.

Prior to operation, somewhat less than average doses of bishydroxycoumarin were needed to produce an effective prothrombin depression. After operation anticoagulant therapy was again resumed, with ethyl biscoumacetate. Unusually large doses were used, and an effective level was not reached in 10 days. Resumption of bishydroxycoumarin therapy demonstrated the fact that the doses needed to produce equal prothrombin depression were much greater than in the preoperative period. The question may be raised whether the vitamin K_1 oxide therapy and/or the blood transfusions may have been operative in producing the relative resistance to the anticoagulant drugs postoperatively.

SUMMARY

Acute appendicitis developed in a patient receiving anticoagulants for an acute myocardial infarction. The methods utilized in the management of this problem, including preoperative and postoperative care, are described.

330 S. 9th St.

SHORT-TERM USE OF CORTICOTROPIN AS ADJUNCTIVE THERAPY

William S. Reveno, M.D.
Herbert Rosenbaum, M.D.
and
John H. Buell, M.D., Detroit

As experience with corticotropin (ACTH) accumulates, it is becoming increasingly apparent that its greatest usefulness is less as a cure in disease states than as an antitoxic agent, bolstering the defense mechanism and promoting remission. This quality may assert itself by the liberation of substances that absorb toxins by strengthening the cell membrane to prevent entry of damaging agents or by preventing disorganization of enzymatic processes within the cell itself. Bacterial growth is not inhibited, and specific antibody formation is neither accelerated nor arrested. The action may be presumed to be mainly one of blocking the action of toxins and allowing an adequate build-up of the defensive processes.

Viewed in this light, the potentialities of the short-term use of corticotropin for conditions in which there is poor response to other therapy becomes readily evident. Systemic infections, shock states, and acute toxemias, when the patient is overwhelmed or floundering, may be brought under control by the addition of this protective agent, as is illustrated in the following instances.

CASE 1.—J. S., a 63-year-old man, was admitted to the hospital on May 16, 1951, with a diagnosis of acute appendicitis and peritonitis. At operation a ruptured gangrenous appendix with purulent peritonitis was found. The appendix was removed, the wound closed, and a cigarette drain placed in the fascial layer. One-half gram of streptomycin and 300,000 units of procaine penicillin were given intramuscularly twice daily. The abdomen remained distended, and the patient started hiccoughing on the second day. The temperature was elevated to 100 F, and the pulse rate ranged from 110 to 120 per minute. Attempts at passing a Miller-Abbott tube were unsuccessful, and the patient was becoming increasingly toxic and exhausted. While administration of the antibiotics was continued and the daily salt intake reduced, 20 mg. of corticotropin was injected at 10 a. m. on the third day and 10 mg. given every 4 hours, for a total of 12 doses in 48 hours. Six hours after the initial dose, flatus was passed for the first time, and the abdomen was less distended. The temperature dropped to 98.8 F, the pulse rate to 100, and the patient was more comfortable. On the following morning he had a liquid bowel movement, with further reduction in the distention; the temperature remained normal, and the pulse rate dropped to 86. The patient took food with relish and appeared much less toxic. The next day he was even more improved, had another liquid movement, and was passing flatus freely; the distention was practically gone. The hiccoughing had now stopped. Improvement continued from this day on, and he was discharged on the 14th day, having made an uncomplicated recovery.

CASE 2.—R. J., a white man, 61, was admitted to the hospital May 18, 1951, with a diagnosis of acute diverticulitis with perforation and generalized peritonitis. Severe pain in the left lower quadrant of the abdomen and temperature of 101.4 F had occurred the evening before. The fever had persisted, and the abdominal tenderness was now marked over the entire lower part of the abdomen.

Conservative therapy was instituted. Continuous tube suction was started, succinylsulfathiazole (sulfasuxidine®) and terramycin were given by mouth, and penicillin and streptomycin injected intramuscularly. The temperature remained elevated during the next week, and it became evident that an abscess had developed in the left lower part of the abdomen. While this area was palpated, the abscess ruptured, and the patient was taken to the operating room, where the abscess was drained and three Penrose drains left in situ.

In spite of seemingly adequate drainage and continued treatment with antibiotics, the temperature and pulse rate remained elevated, and the patient was making no progress. On the fifth day an injection of 20 mg. of corticotropin was given, followed by a 10 mg. dose every four hours for a total of 12 doses. Six hours after the first injection the temperature dropped to normal, and the patient reported an increased sense of well-being. He improved rapidly from this point and was discharged on June 4th, nine days after operation.

CASE 3.—A. B., a white man, 65, was admitted to the hospital April 20, 1951, because of severe knife-like pain in the right side of the chest of one week's duration. The night before admission he had a slight chill, and the pain became much severer. The temperature was 100.2 F, the pulse rate 100, and there was evidence of pleural effusion over the right lung base. There was very little cough and no hemoptysis. The white blood cell count was 10,600, with 79% polymorphonuclears, 9% lymphocytes, 9% mononuclears, and 3% eosinophils. X-ray study on April 21 showed evidence of right lower lobe pneumonia with associated effusion.

On April 21 and 22 the pleuritic pain became more intense, dyspnea was marked, and there was slight cyanosis. Strapping of the chest made the pain worse, and intercostal nerve block produced only temporary relief. Thoracentesis was done on April 23d, and only 15 cc. of cloudy orange-colored fluid was obtained. This showed principally mature polymorphonuclears, with many very large and often multinucleated histiocytes. Blood and pleural fluid culture showed no growth. Dulness was now present over both lung bases, and the pain, dyspnea, and cyanosis, with elevated temperature, persisted in spite of continuously administered oxygen and frequent use of anodynes. Use of penicillin and streptomycin, 300,000 units and 0.5 gm. respectively, was started twice daily.

On April 24, with the condition and treatment unchanged, the first injection of 20 mg. of corticotropin was given, and this was repeated every four hours for 12 doses. Six hours after the first dose the pain had stopped, the respirations had slowed, and their depth had increased. By the next morning improvement

---

From the Departments of Medicine and Surgery, Harper Hospital.

was even more marked; the temperature was normal, the breath sounds over the lung bases were louder, and crepitant rales were heard for the first time. There was no more dyspnea or pain during the period of corticotropin administration, but five hours after the last dose was given the pain and dyspnea recurred. Corticotropin was given again, this time in a dosage of 20 mg. every six hours, and again there was dramatic disappearance of the disturbing signs. Use of the drug was continued for the next six days at the same dosage level; administration was decreased on the seventh day to 15 mg., on the eighth day to 10 mg., and on the ninth day to 5 mg. every six hours, then discontinued. This time the improvement persisted, and, while there were occasional fleeting chest pains, the signs of effusion gradually disappeared.

X-ray studies on April 28 showed increased fluid in the basilar section of the right thorax, obscuring the lower part of the right lung. Two days later an area of consolidation was evident, which surrounded pleural thickening of the right lower lung field highly suggestive of infarct. After another four days the localized area of consolidation just above the right leaf of the diaphragm again showed no change. One area of rarefaction, without definite fluid level, was seen within the center of the lesion. The left costophrenic angle was now obliterated, suggesting accumulation of fluid here. A final x-ray on May 11 showed slight progress in resolution of the lesion in the lower third of the right lung.

On May 7, four days after use of corticotropin was discontinued, marked pain and tenderness in the calf of the left leg developed, and bilateral femoral vein ligation was performed by Dr. E. A. Osius. Recovery from the operation was uneventful, the chest signs continued to improve, and the patient was discharged May 14, 1951, 25 days after admission.

SUMMARY

In the first two patients, both with purulent peritonitis, response to therapy was indifferent and little, if any, progress was being made toward recovery. Administration of corticotropin (ACTH) for 48 hours, while use of antibiotics was continued, provided the necessary stimulus that tipped the scales toward a prompt favorable outcome. The third patient, with severe pain, dyspnea, and toxemia from pulmonary infarction, responded promptly to 48 hours' treatment with corticotropin but showed return of symptoms when it was stopped. The condition improved and recovery followed when the corticotropin therapy was resumed and continued for another six days. Accordingly, in these three patients, the value of the short term use of corticotropin for conditions in which there is poor response to other forms of therapy has been demonstrated.

968 Fisher Bldg. (Dr. Reveno).

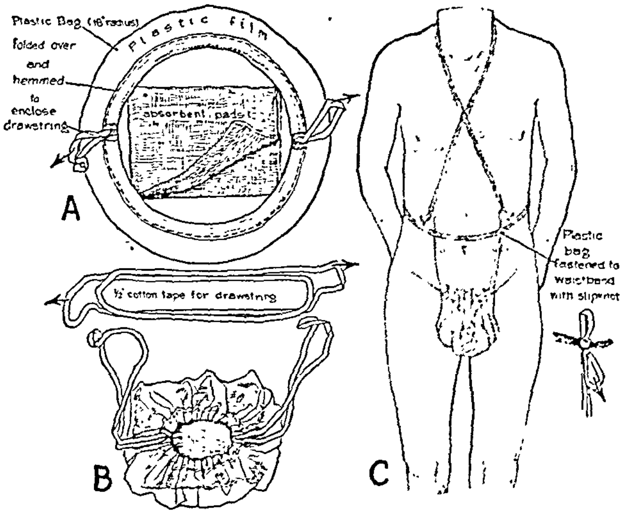
Meaningless Phrases.—In its proper proportion description of a disease entity is only the first step, and a small one at that, toward understanding of etiology, pathogenesis, and treatment. There is no disease which is thoroughly understood; often specific therapy does more to stifle progress in this respect than any other single factor. Insulin effectively stopped research on the etiology and pathogenesis of diabetes for twenty years; the antibiotics may be doing the same for infectious diseases. Medical science, still in its childhood, continues to describe new disease entities, which is progress. But when we are tempted to use meaningless phrases, or what is worse, the names of men, as descriptions, we are taking semantic refuges from the realities of ignorance. "Essential" hypertension, idiopathic thrombocytopenia, Loeffler's syndrome are examples. "Essential" means "I don't know." I have always preferred the word "agnogenic," which really says, "I don't know." Let us not be afraid to admit our ignorance, and qualify words with that humble admission, thereby making a challenge of a refuge.—Henry A. Schroeder, M.D., Knowledge, Faith and Humility, *The Centaur of Alpha Kappa Kappa*, May, 1952.

PLASTIC BAG FOR URETHRAL LEAKAGE CONTROL AFTER PROSTATECTOMY

Thomas S. Cullen, M.D., Baltimore

In March, 1950, Dr. Howard C. Smith removed the central lobe of my prostate at the Church Home and Hospital. He described it as the largest central lobe he had ever encountered in surgery; the weight was 254 gm. The posterior incision healed by first intention; nevertheless, there was a great amount of leakage from the urethral orifice, evidently due to laxness after removal of the large tumor.

As soon as I was well enough, Mrs. Cullen, a graduate of the Johns Hopkins Hospital School of Nursing, undertook control of the leakage. She selected a waterproof plastic,[1] so soft that it could hardly be felt. She made a round bag of this material sufficiently large to contain the genitalia, with a wide hem through which to draw tapes.



Plastic Bag (18" radius)
Plastic film
folded over and hemmed to enclose drawstring
absorbent pads
A
½" cotton tape for drawstring
B
C
Plastic bag fastened to waistband with slipknot

A, top view of plastic bag showing placing of drawstrings and absorbent pads. *B*, drawstrings drawn tight so that the bag would completely cover the genitalia. (The tighter the strings are drawn, the better.) *C*, bag in place. To prevent the bag from slipping down in the back, the two ends of the drawstrings should be fastened laterally, as far as possible, instead of near the front as indicated in the drawing.

Two absorbent pads were placed in the bag, the bag was placed around the genitalia, and the tapes were drawn tight enough to prevent leakage. Each tape string was then tied to the side of the abdominal girth (made of gauze bandage) by slipknots, which could be easily untied. The girth was held firmly by another gauze bandage placed around the neck, crossed over the chest, and tied on each side of the girth (see figure).

The plastic bag can be removed whenever necessary, usually every two or three hours during the day, and replaced by a fresh one with dry pads. At night, a urinal may be used when required. When the patient gains strength, he can remove and replace the bag without assistance.

20 Eager St. (2).

TORULOSIS (CRYPTOCOCCOSIS) PRODUCING A SOLITARY PULMONARY LESION

REPORT OF A FOUR YEAR CURE WITH LOBECTOMY

Morris Berk, M.D.
and
Bruno Gerstl, M.D., Oakland, Calif.

Torulosis, or cryptococcosis, is an often fatal disease due to a yeast-like organism and having a predilection for the central nervous system, with the lungs as the second commonest site of involvement. It has been considered a rare disease, but many cases are probably overlooked, owing to the lack of its consideration in the differential diagnosis, failure to culture the organism on suitable mediums for sufficiently long periods of time, and frequent confusion of the organism with lymphocytes or red blood corpuscles in the spinal fluid.[1] Notwithstanding, a total of nearly 200 cases have now been reported.[2] Of this number, only five cases of solitary lung involvement are on record (see the accompanying table).[3] To this meager group we add a sixth, which is considered worthy of publication not only because of its rarity but also because it simulated tumor of the lung, eventually leading to thoracotomy. Other authors have mentioned similar experiences.[4] For this reason attention is hereby again directed to the necessity for consideration of torulosis in the differential diagnosis of circumscribed pulmonary lesions. Also, inasmuch as there is no specific therapy and since pulmonary involvement may actually precede dissemination, there is a growing tendency to consider surgical resection in all cases of pulmonary cryptococcosis. Thus, Taber[4b] has stated that "the early surgical removal of a circumscribed area of torulosis seems as logical as the early removal of carcinoma." Our case would tend to bear this out.

Cases of Solitary Pulmonary Cryptococcosis Found in the Literature

Author	History	Roentgen Findings	Method of Diagnosis	Outcome and Comment
Sheppe[3a] (1921)	Age 50; white male; 4-month illness with tonsillitis, neck stiffness, and weight loss; eventual development of signs of consolidation at right lung base	Initial x-ray normal (no additional x-rays)	Culture of pulmonary tissue at necropsy	Death; brain and meninges apparently not examined; no report of spinal fluid examination
Hardaway and Crawford[3b] (1935)	Age 33; white male; cough only symptom	Multiple nodular lesions; 15-mo. follow-up disclosed little change	Smear and culture of sputum	No essential change during 15-mo. observation
Greening and Menville[3c] (1947)	Age 24, Negro; chest pain, cough, and hemoptysis	Patchy consolidation of upper lobe of left lung and enlargement of bronchopulmonary lymph nodes; confluence of patchy areas with cavity formation and pleural effusion; fibrosis one year after onset	Smear and culture of pleural fluid	Eventual improvement with potassium iodide, antibiotic, and roentgen therapy; alive after one year
Moody[3e] (1947)	Age 38, Mexican; suspected tuberculosis; bronchoscopy revealed "tracheal tumors"	Submiliary lesions	Culture of tissue at necropsy	Asphyxial death
Froio and Bailey[3d] (1949)	Age 19; asymptomatic pulmonary lesion discovered by x-ray at Army induction; referred to tuberculosis sanitarium (negative findings); eventual pneumonectomy for possible bronchogenic cancer	"Mass-like" lesion in lower lobe of right lung	Histological examination of surgical specimen	Circumscribed, rubbery lesion, 4.5 cm. in diameter; alive 5 yr. 7 mo. after surgery without dissemination or recurrence

REPORT OF A CASE

A 30-year-old white World War II veteran, who was receiving compensation for bronchial asthma, was admitted to the Veterans Hospital, Oakland, Calif., on Oct. 31, 1947. Since 1944, when on the island of New Britain in the Southwest Pacific, he had been having infrequent episodes of cough, fever, substernal tightness, wheezing, night sweats, and malaise. He was given a medical discharge from the Army in March, 1945, with a diagnosis of bronchial asthma. After discharge and until his present hospitalization, he had several additional episodes. They were nonseasonal, and each lasted about a week. Five months prior to this hospital entry, during a health survey, a roentgenogram showed a "spot" in the left lung. He was referred to his private physician and eventually to this hospital. The patient, however, was asymptomatic until three days before hospitalization, when he noted the onset of pleural pain over the left side of the chest, malaise, feverishness, and dry cough. There were no chills, hemoptysis, or weight loss. He had had dengue while in the Southwest Pacific in 1943 and seasonal rhinitis since 1945. A maternal grandparent had asthma. There was no history of tuberculosis or of exposure to it.

Physical examination revealed a moderately ill, robust-appearing, white man with a moderate, dry, hacking cough. Respirations were not labored or wheezy. There was no cyanosis or clubbing of the fingers. Oral temperature was 100 F. The pulse rate was 96, respiratory rate 24, and blood pressure 120/88. There were no meningeal signs, skin lesions, lymphadenopathy, or hepatosplenomegaly. The percussion note was resonant throughout. Breath sounds were essentially normal, except at the left lower portion of the chest anteriorly and the lower axilla, where numerous medium and fine rales were heard. No alteration of fremitus or voice sounds was noted.

Laboratory Data.—The white blood cell count was 18,700, with 72% polymorphonuclear cells, 9% stab forms, and 4% juvenile forms. The red blood cell count was 4,700,000, with 14.3 gm. hemoglobin per 100 cc. The sedimentation rate was 95 mm. (Westergren). Results of examination of the blood for cold agglutinins were negative. Results of liver function tests were normal. Blood culture was sterile. Concentrated sputum collections and gastric wash were negative on smear and culture and in a guinea pig test for tuberculosis. The coccidioidin skin re-

action was negative; a test with second strength purified protein derivative yielded a positive result. Bronchoscopy disclosed a normal condition throughout, and bronchial secretions were negative for tumor cells. The initial chest x-ray (fig. 1) revealed a density occupying the anterolateral and lower portions of the upper lobe of the left lung, just above the interlobular fissure. A subsequent x-ray revealed some increase in size of this shadow, with the addition of a small amount of pleural fluid (fig. 2). Bone survey and excretory pyelograms were normal, a bronchogram of the left side showed moderate cylindrical bronchiectasis in the lingular region. However, bronchi extending to the lesion in question appeared normal.

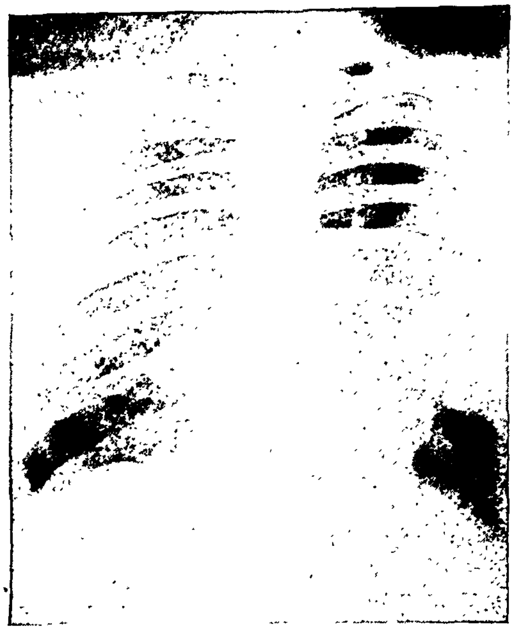

Fig. 1.—Initial roentgenogram, showing circular density in left mid-lung field.

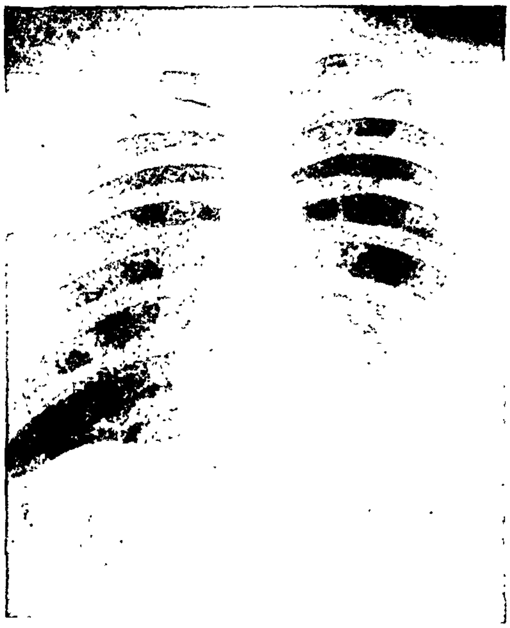

Fig. 2.—Roentgenogram taken 10 days after the first (fig. 1), with more circumscribed outline of the density and the addition of pleural effusion.

Clinical Course.—A tentative diagnosis of pneumonia was made, and the patient was treated with penicillin and sulfadiazine but without response. He continued to have fever, his temperature ranging from 99 to 101.6 F. On the eighth day after entry there was a sudden increase of pain in the left lateral portion of the chest, with physical signs of fluid, accompanied by a pleural friction rub. By thoracentesis 200 cc. of serosanguineous fluid was removed. The sediment of this fluid showed numerous cells of endothelial character. In view of the lack of response to chemotherapy with progression of the lesion seen on x-ray, the case was reviewed by the tumor board, and surgical exploration was advised. A tentative diagnosis of tumor was made. Thoracotomy was performed by Dr. David Dugan, consulting chest surgeon, five weeks after the patient's admission to the hospital, and a large tumor mass in the upper lobe of the left lung was removed by lobectomy. The tumor on frozen section was diagnosed as mycotic granuloma. The patient made an uneventful postoperative recovery and was discharged approximately two weeks later. He was still living, without evidence of recurrence or dissemination of his disease, four years later.

Description of Specimen.—Gross: The pleura of the removed upper lobe of the left lung was intact except over an oval-shaped area of the lower lateral segment, which had a dull yellow appearance. Sectioning revealed an oval-shaped, firm, tumor-like, fairly well-encapsulated, grayish yellow mass with a mucoid surface. It measured 7 by 6 by 6 cm. and corresponded in location to the pleural lesion. The remaining pulmonary parenchyma was unremarkable.

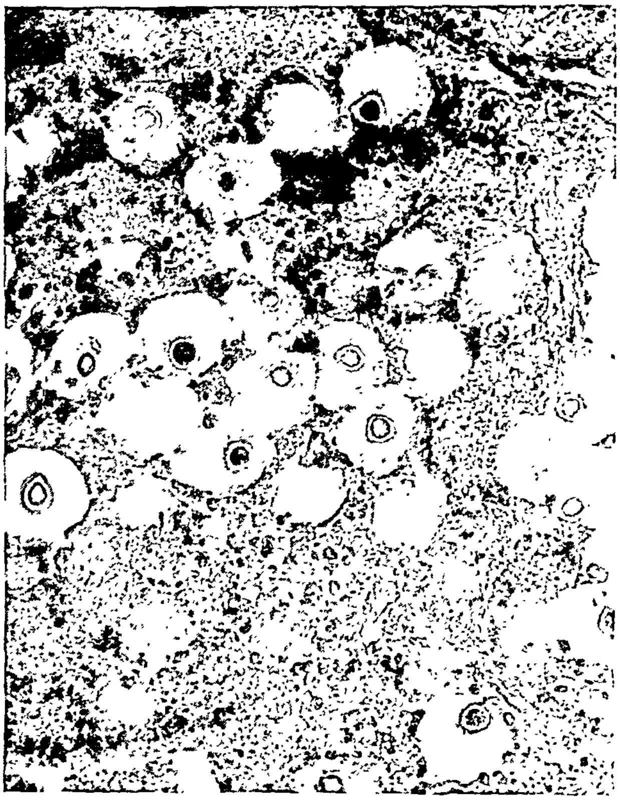

Fig. 3.—Cryptococcus organisms in lung lesion, with characteristic structure and wide refractile capsule (× 230).

Microscopic: Sections representing the peripheral areas of the lesion revealed fairly dense connective tissue infiltrated by small round cells. The adjacent alveoli were compressed. In

W.: Tumor of Lung Due to Cryptococcus Histolyticus (Blastomycosis), J. Thoracic Surg. **14**: 322-329 (Aug.) 1945.

some areas the parenchyma, including blood vessels, had undergone necrosis. There were cellular debris and fine pink-staining fibers with numerous circular clear spaces. Many of the latter contained round bodies whose centers stained grayish pink and which were highly refractile. Their light pink broad peripheral zone suggested capsule formation (fig. 3). Two nearby bronchial lumina were largely occluded by granulation tissue containing a few multinucleated giant cells. With Kernohan's method,[5] the micro-organisms stained bright pink with pale yellow in the periphery. Sabouraud's medium was inoculated with fresh tissue but remained sterile. India ink preparations of imprints demonstrated a thick capsule.

COMMENT

A review of the literature shows the frequency with which pulmonary cryptococcosis presents itself as a circular, circumscribed density, usually associated with meningeal involvement, or occasionally just preceding such involvement.[6] Pulmonary lesions are said to occur in two forms: either as gelatinous masses or as fibrotic granulomatous lesions. In the first type there is massive proliferation of cryptococci into a gelatinous mass. In the second type there is a paucity of organisms. The miliary nodule, which resembles a tubercule both grossly and microscopically, is the commonest pathological lesion.[7] Greening and Menville [3c] found four cases of torulosis in 537,135 admissions to the Charity Hospital in New Orleans. In three there was pulmonary involvement, followed with serial roentgenograms. From their observations and review of the literature, they noted that the disease had a predilection for the lung bases. In early cases there were circumscribed patches of homogenous consolidation with only a small amount of surrounding reaction. These areas tended to become confluent, occasionally progressing to cavity formation. With healing there was fibrosis. Slight hilar enlargement was sometimes noted.

The portal of entry of torulosis is as yet obscure. Most observers consider it to be the lung. The disease is probably carried to other organs via the blood and lymph channels. Wade and Stevenson's [8] work indicates that the disease passes through a septicemic stage. They were unable to produce central nervous system involvement without visceral involvement (chiefly lung and kidney) when they inoculated white mice intracerebrally, intravenously, intraperitoneally, intratracheally, and subcutaneously. Intranasal inoculation caused only severe rhinitis or sinusitis. Organisms spread out beneath the cribriform plate but did not invade the central nervous system. These studies suggest initial pulmonary involvement and thus the probable importance of early resection.

SUMMARY

A case of solitary pulmonary torulosis simulating tumor is hereby added to the literature as the sixth case on record. The patient is alive, without recurrence or dissemination of the disease, four years after lobectomy. The lung may be the portal of entry of this highly fatal disease. For this reason, surgical excision is recommended as a curative measure prior to dissemination. Torulosis should be considered in the differential diagnosis of circumscribed nodular pulmonary lesions.

AGRANULOCYTOSIS OCCURRING DURING PHETHENYLATE ("THIANTOIN") SODIUM THERAPY

Allen E. Hussar, M.D.
and
Helen B. Rogers, M.D., Tuscaloosa, Ala.

Putnam and Merritt's method of testing the anticonvulsant activity of drugs in animals opened an era of intensive search for more effective drugs with which to control epilepsy.[1] Innumerable chemical substances were tested, and, beginning with diphenylhydantoin sodium, several were subsequently introduced into clinical practice.

Whereas some of the new anticonvulsant drugs are now considered valuable additions to the therapeutic armamentarium for epilepsy, their toxic side-effects create a certain amount of hazard in the treatment of this disease. There have been reports of the occurrence of bone marrow depression, exfoliative dermatitis, nephrosis, and hepatitis, with recoveries and fatalities. Apparently depression of the blood elements is the commonest among these serious complications. In 1950, Abbott and Schwab noted that there had been 25 fatal reactions in the previous four years, which occurred during trimethadione, methylphenylethyl hydantoin, or phenacemide administration; 15 of the patients died with aplastic anemia or pancytopenia (6 during methylphenylethyl hydantoin, and 9 during trimethadione therapy).[2] Since then we have found additional reports of pancytopenia and death from methylphenylethyl hydantoin therapy (one case)[3] and from phenacemide therapy (two cases).[4] While paramethadione therapy may also cause bone marrow depression in susceptible patients,[5] no serious cases have been reported.

Phethenylate ("thiantoin") is one of the newest drugs with anticonvulsant properties. It was prepared in 1941, and preliminary clinical trials began in 1942. In 1947, Peterman reported on 73 children treated with this drug.[5a] He observed as side-reactions hypertrophy of the

gums in two cases, ataxia in four cases, and rash caused by the drug in two cases. The drug has been used in over 40 cases at the Illinois Neuropsychiatric Institute without any notable blood changes.[6] In 1950, Best and Paul reported a case of severe hypoplastic anemia with recovery occurring during diphenylhydantoin sodium, methylphenylethyl hydantoin, and phethenylate administration.[7] In 1951, Weiss and Hawley described a case of fatal pancytopenia following the use of methylphenylethyl hydantoin and phethenylate.[8] The part that phethenylate played in the production of these toxic accidents cannot definitely be stated, since in both cases this drug was given simultaneously with methylphenylethyl hydantoin, a known depressant of the hematopoietic system. In order to furnish the first known direct evidence of toxic effects of phethenylate on the bone marrow, we consider it of interest to report a case of agranulocytosis in a patient during administration of this drug.

REPORT OF A CASE

E. J., a 37-year-old divorced woman, was admitted to the neuropsychiatric service on Aug. 17, 1951. She had a history of life-long inadequacy and dependency. The onset of her psychosis was insidious and extended over a period of years. On admission, the physical examination showed nothing essentially abnormal. A routine blood cell count showed 4,500,000 red blood cells, 12.5 gm. of hemoglobin, and 5,400 white blood cells, with a differential count of 62% neutrophils, 3% eosinophils, and 35% lymphocytes. Psychiatric observation revealed that the patient was actively hallucinating; she was confused and disoriented as to place and often got lost in the ward. Her speech was incoherent, irrelevant, and showed marked delapidation of thoughts.

A course of deep-coma insulin treatment was started, which had to be discontinued because urticaria and angioneurotic edema developed. This allergic reaction to insulin also reappeared when zinc insulin was substituted for crystalline insulin. Treatment, therefore, was changed to electric shock therapy. The patient's condition became worse, and she started to complain of severe headaches. With this new symptom and a history of an old head injury, an electroencephalogram was made. The tracing showed abnormalities compatible with psychomotor epileptic discharge, idiopathic rather than of focal origin. Anticonvulsant therapy was recommended by the electroencephalographer, and on Nov. 1 treatment with phethenylate sodium, 2 grains (0.13 gm.) twice a day, was started. Soon after this treatment was instituted, definite improvement was observed in the patient's mental condition. The headaches subsided, and she seemed less confused. No routine blood cell counts were made during medication. The patient had received no other drugs since her admission to the hospital.

On Nov. 19, the 19th day of phethenylate therapy, the patient complained of being cold and aching all over. Her temperature was normal, and symptoms subsided spontaneously. On Nov. 21, she had a severe chill lasting over an hour, followed by a temperature of 105.4 F rectally. On Nov. 22, she felt comfortable except for vomiting after lunch. The maximal temperature on that day was 103 F.

On Nov. 23, the patient again had a chill, followed by a temperature of 104.8 F. At this time a medical consultation was requested. The patient had no symptoms, and she appeared cheerful and alert. Physical examination revealed a slight pallor of the skin but none of the mucous membranes. The throat was clear. There was a single area of ecchymosis of the conjunctiva of the right eye; otherwise the skin and mucous membranes were clear. No enlarged lymph nodes were palpable. The spleen was palpable on deep inspiration, but results of the rest of the physical findings were negative.

A roentgenogram of the chest was normal, and results of urinalysis and malaria smears were negative. A blood culture was taken and later reported sterile. A complete blood cell count showed 2,200 white blood cells with 51% neutrophils and a shift to the left. The red blood cell count, hemoglobin, and platelet count were normal. The diagnosis of granulocytopenia due to phethenylate sodium therapy was made.

Beginning Nov. 24, the patient was free of symptoms and felt well during the rest of the observation period, with the temperature remaining normal. Her subsequent course was characterized by changes in the blood cell count (see the accompanying table).

The total white cell count fell to its lowest level, 1,500, on Nov. 26 (the sixth day of illness), and granulocytes were completely absent in the peripheral count on Nov. 28 (eighth day). On that day a sternal puncture was done for a bone marrow study. The differential cell picture of the bone marrow showed a disturbance in maturation at the myelocyte level consistent with the diagnosis of granulocytopenia due to drug sensitivity. There was an increase in granulocytic myelocytes. The myeloid-erythroid ratio was found to be 1: 1.24. The megakaryocytes were normal and the platelets plentiful.

Neutrophils reappeared in the peripheral blood on Nov. 29 (9th day) and reached 50% in a 5,200 total white blood cell count on Dec. 4 (14th day). The peripheral red cell count did not show any abnormalities except for a transient 15% drop on the fifth and sixth days of illness. The platelet count remained normal throughout the entire period.

Phethenylate therapy was discontinued after the first blood cell count, Nov. 23 (third day), and treatment then consisted of the administration of procaine penicillin, 600,000 units once daily, and bed rest. In anticipation of pancytopenia, because of the red cell drop, blood transfusions were started on Nov. 25 and given for five consecutive days. Retrospectively, however, we do not believe that erythropoiesis was impaired in this case or that the transfusions played any role in the recovery of the patient.

Changes in the White Blood Cell Count in the Reported Case

Date (1951)	Day of Illness	White Blood Cell Count	Neutrophils, %	Lymphocytes, %
11/23	3	2,200	51	44
11/25	5	2,200	4	96
11/26	6	1,500	3	97
11/27	7	2,100	1	99
11/28	8	2,100	0	100
11/29	9	2,000	1	99
11/30	10	2,300	2	98
12/ 3	13	4,000	48	52
12/ 4	14	5,200	50	48

COMMENT

Apparently all the newer anticonvulsants are capable of depressing bone marrow in an occasional case. Only diphenylhydantoin sodium seems to be an exception to this. It is beyond the scope of this report to discuss in detail the control and prevention of the serious side-effects of the newer antiepileptic drugs, a topic comprehensively presented by others.[9] The advisability of frequent blood cell counts during the administration of the newer anticonvulsants, however, is emphasized.

SUMMARY

Agranulocytosis developed in a patient on the 20th day of administration of phethenylate ("thiantoin") sodium, 2 grains (0.13 gm.) twice a day. After cessation of treatment with the drug, the patient promptly recovered.

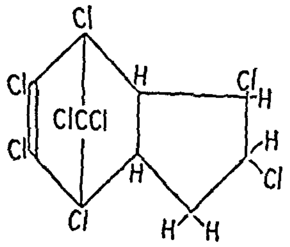
INTOXICATION DUE TO CHLORDANE

REPORT OF A CASE

G. Bruce Lemmon Jr., M.D., Springfield, Mo.
and
Commander Wilmot F. Pierce (MC), U.S.N.

Chlordane is a commonly used insecticide with the empirical formula $C_{10}H_6Cl_8$ and the following structural formula.



Stohlman, Thorp, and Smith[1] have reported that it causes acute toxicity in rabbits equal to that caused by dichlorodiphenyltrichloroethane (DDT), a similar compound, in equivalent oral dosage ($L.D._{50}$), and that it causes greater chronic toxicity than does this similar compound because of greater cumulative action. Lehman[2] reported that toxicity in rats occurred after 12 weeks' administration of chlordane, 250 parts per million in the diet, the lowest intake causing gross demonstrable defects, whereas the toxic dose of dichlorodiphenyltrichloroethane was only 100 parts per million, but this required administration for 104 weeks. In dogs, administration of chlordane, 660 parts per million, caused death in four weeks; 2,640 parts per million of dichlorodiphenyltrichloroethane was necessary over a similar period. As with dichlorodiphenyltrichloroethane, continuous administration of chlordane to laboratory animals caused focal hepatic necrosis, edema, congestion and exudates in the lungs, and degenerative changes in intestinal submucosa and in the convoluted tubules of the kidneys. Organically bound chlorine was demonstrated in the urine of these animals. Bushland, Wells, and Radeleff[3] reported that, when chlordane was applied to cattle, hogs, sheep, and goats by spraying or in dips, signs of neurological and hepatic damage and subserosal hemorrhages resulted.

Statements by some investigators indicate the possibility of human intoxication from chlordane. Lehman[2] reported that the mean lethal dose of this compound in man is half that of dichlorodiphenlytrichloroethane and that smaller amounts than those of dichlorodiphenyltrichloroethane can be dangerous to man, in both divided and single doses. Hine[4] stated, "The halogenated hydrocarbons affect, in large amounts, the heart or central nervous systems, just as does chloroform; and in small amounts, if given over a period of time, produce liver and kidney damage, as does chloroform." On the other hand, Princi and Spurbeck,[5] in a study of 22 workers exposed to chlordane, aldrin, and dieldrin (compounds similar to chlordane) in the manufacture of these compounds, found no evidence of toxic effects as indicated by history, physical examinations, or laboratory tests. The men worked in atmospheres having up to 54 mg. of chlorinated hydrocarbons per cubic meter and were protected only by rubber gloves. Poisoning by swallowing an aldrin mixture has been reported by Spiotta.[6]

A review of the available medical literature has revealed no specific instance of chlordane causing toxic reactions in man. In the following case there was evidence of injury to the lungs, liver, and hematopoietic system after inhalation of chlordane.

REPORT OF A CASE

A 33-year-old Caucasian housewife was admitted to the United States Naval Hospital, San Diego, Calif., complaining of nausea, vomiting, and cough. She had been well until approximately one week previously, when a mildly acute infection of the upper respiratory tract had developed. Two or three days later, she entered her apartment at about 9:30 p. m. and noticed strong fumes of an insecticide, with which the apartment had been sprayed several hours earlier. She never opened her windows at night, fearing burglars, and she retired without airing the rooms. About 3 a. m. she awoke with severe cough and vomiting, and these symptoms continued unabated until admission four days later. The cough produced a moderate amount of thick, white sputum, which diminished in quantity. She did not complain of pain; nausea and vomiting were the only symptoms referable to the gastrointestinal tract. Past history was significant only in that, during an admission five months previously, after cerebral concussion, she had had an epileptiform seizure, the only one of her life; no abdominal organs were palpable at that time. She had returned from a prolonged stay at Guam 18 months prior to the last admission but had not been ill while there. She admitted occasional evenings of alcoholic intake of six or seven highballs but denied having had any alcohol for some time prior to the onset of this illness. The patient's private physician gave the information that she was a periodic "binge" drinker and that he was called to see her a few hours after she became ill by a woman friend of the patient, who was herself obviously intoxicated. He did not see or talk with the patient but suspected she also was intoxicated. She steadfastly denied this. It was ascertained that the insecticide used in the apartment was 1% or 2% chlordane, probably in an oil base similar to kerosene, used in an ordinary insect spray gun.

The patient was an alert, well-developed, slightly obese woman, appearing moderately ill and coughing frequently. Temperature, pulse, respiration, and blood pressure were normal. Physical findings were entirely within normal limits except for a smooth, firm, slightly tender liver edge, which descended three fingerbreadths below the right costal margin on inspiration. Breath sounds, voice sounds, and resonance were normal throughout both lungs, and no rales or rhonchi were heard. No telangiectasia and no lymphadenopathy were noted.

On admission the urine was normal. The Kahn reaction of the blood was negative, and the heterophil agglutination (not absorbed on guinea pig tissue) was positive in a titer of 1:14. Other admission laboratory findings are included in tables 1 and 2. The chest was within normal limits according to roentgenographic examination.

The opinions or assertions contained herein are the private ones of the writer and are not to be construed as official or reflecting the views of the Navy Department or the Naval Service at large.

The patient was afebrile throughout and showed rapid improvement. The cough was nonproductive on admission. Three days after admission the cough and emesis had practically ceased, and five days later the liver was no longer palpable. The only treatment was the administration of fluids parenterally on admission, hepatitis diet, and codeine for the cough. She was discharged 10 days after admission and was told to continue to have blood cell counts and liver function tests as an outpatient (tables 1 and 2). Unfortunately, blood drawn on Feb. 2, 1951, for a complete blood cell count clotted in the oxalate tube, and thereafter the patient failed to return to the hospital.

COMMENT

The pulmonary exudation exhibited by this patient and the hepatic dysfunction demonstrated by sulfobromophthalein retention and moderately positive cephalin flocculation are consistent with the toxic changes found to result from chlordane poisoning in animals. Hematologic reactions to dichlorodiphenyltrichloroethane have been reported,[7] including agranulocytosis from aerosol use, so that it is entirely possible that a similar compound, chlordane, caused a like reaction in this patient, with persistent depression of granulocytes, in one determination to 19%. The anemia was normocytic and hypochronic, and normal reticulocyte count and serum bilirubin concentration militate against hemolysis; the cause of the anemia is undetermined.

It might be argued that the blood picture and liver dysfunction were simply the result of cirrhosis in an alcoholic person in view of the slightly lowered albumin-globulin ratio (1.5:1), anemia, and leukopenia. However, the anemia was not macrocytic (mean cell volume, 94) as Tumen[8] stated is the tendency in cirrhosis, and the leukopenia was actually neutropenia. The serum albumin (3.8 gm.) per 100 cc. was only slightly lowered if at all (one source[9] quotes 3.5 to 5.6 gm. as normal, while others[10] give 4 gm. as the minimum normal value), and this is hardly valid evidence of cirrhosis. It should be noted also that hepatomegaly was not observed at the time of the patient's admission five months previously. Further, the liver enlargement found on this admission was no longer discernible after a few days and the degree of sulfobromophthalein retention diminished rapidly, indicating an acute process. Spider nevi and palmar flush were not seen.

† No abnormal lymphocytes reported.

In an editorial in THE JOURNAL[11] it was indicated that fat soluble chlorinated hydrocarbons, such as chlordane, are stored in adipose tissue and in the fat of all parenchymal cells, interfering with enzymatic processes in these cells. In view of this patient's obesity and the fact that she had definite alcoholic tendencies, it might be surmised that she had at least some increase in fat deposition in the liver, which could have made her more susceptible to hepatic insult.

It is unlikely that the abnormalities in this patient could have been caused by the solvent rather than by chlordane. The Council of Pharmacy and Chemistry of the American Medical Association in a report on dichlorodiphenyltrichloroethane[7] authorized the following statement: "The signs of solvent intoxication set in promptly, in contrast to the latent period of several hours required for the development of DDT symptoms." Approximately six hours intervened between the onset of the patient's exposure and development of cough and vomiting. It has also been stated[12] that xylene, kerosene, and other solvents may cause "irritation and other local symptoms, but are of minor importance when compared with the danger of system toxicity," referring particularly to the cutaneous absorption of aldrin and dieldrin, compounds similar to chlordane. It is possible that this patient's productive cough was due to bronchial irritation from the solvent fumes but hardly likely that such irritation would have caused a cough of over a week's duration. The hepatic and hematologic reactions could hardly have been due to solvent intoxication. Unfortunately, the patient was lost to observation before laboratory studies indicated a complete return to normal hepatic and hematopoietic functions.

CUTANEOUS ALLERGY FROM LOCAL CONTACT WITH ISONICOTINIC ACID HYDRAZID

James W. Jordon, M.D., Buffalo

Isonicotinic acid hydrazid and its isopropyl derivative have recently been introduced for the treatment of tuberculosis. Because these drugs will find a widespread use, I believe the following report of a case of cutaneous sensitivity from local contact with isonicotinic acid hydrazid is of considerable interest. As far as I know, this is the first report of such a case.

REPORT OF A CASE

A white man, aged 34, a pharmaceutical chemist, was first seen on May 2, 1952, with the chief complaint of a skin eruption on his hands that had started on March 24, 1952. He stated that the only new product he had worked with prior to the onset of the eruption was isonicotinic acid hydrazid. He first worked with this drug on March 10, 1952. Because of the severity of the eruption he discontinued work from April 11 to April 21, and during this interval the rash had improved. On returning to work the eruption again became severe. When he was examined on May 2, 1952, he had an acute vesicular confluent dermatitis venenata involving the dorsal surface of both hands, the dorsal and ventral surface of both wrists, and to a slight extent the anterior aspects of the face and sides of the neck. He was asked to discontinue work because of the severity of the eruption and to bring in samples of the isonicotinic acid hydrazid as well as all other chemicals he had worked with prior to the onset of the dermatitis. He did this on May 20, and patch tests were made with the chemicals. At the end of 48 hours he showed a 4+ vesicular reaction to a tablet containing isonicotinic acid hydrazid. All other substances with which he was tested gave negative results. Because the tablet contained fillers and binders, he was asked to bring all the separate ingredients of the tablet for further patch test studies, and these were done on May 26, 1952. At the end of 48 hours he showed a vesicular reaction to the isonicotinic acid hydrazid, the other ingredients of the tablet giving negative results. Since discontinuing work and avoidance of contact with isonicotinic acid hydrazid, his dermatitis has gradually subsided. He was last seen on June 2, 1952, and was almost free of his eruption.

COMMENT

The development of the dermatitis venenata from local contact with isonicotinic acid hydrazid shows that this drug can induce epidermal sensitization if it contacts the skin. This means that in others who handle the drug, such as pharmacists, physicians, nurses, or patients, cutaneous sensitivity and dermatitis venenata may develop from local skin contact with it, and it should be suspected as a cause of unexplained dermatitis venenata in such persons.

PLASTIC COMPRESSOR FOR ENUCLEATION AND EVISCERATION

Conrad Berens, M.D., New York

An "enucleation compressor" devised by Anthony,[1] was found to be most practical in controlling bleeding during enucleation and evisceration. The modification of the Anthony compressor herein described [2] is lighter and, because of the wicket shape, is easily manipulated. The instrument is made of lucite® (polymerized methyl methacrylate), with two arms bent at an angle of 45 degrees to the central grip. The central grip, which is 10 cm. long and 16 mm. in diameter, affords a comfortable hold. The arms of the plastic compressor are 9 cm. in length and taper in diameter from 16 mm. to 4 mm. The arms terminate in ovoid compressor tips, one 14 mm. and the other 11 mm. in diameter (fig. 1). The compressor is light in weight, inexpensive and may be sterilized in the usual manner for other plastic materials.

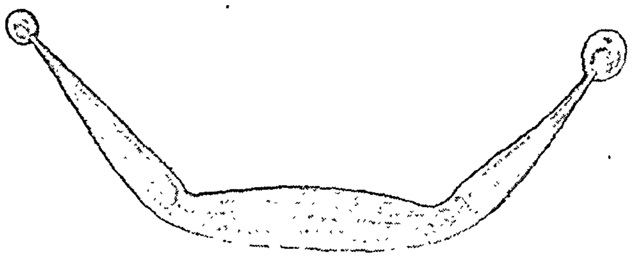

Fig. 1.—Plastic compressor for enucleation and evisceration.

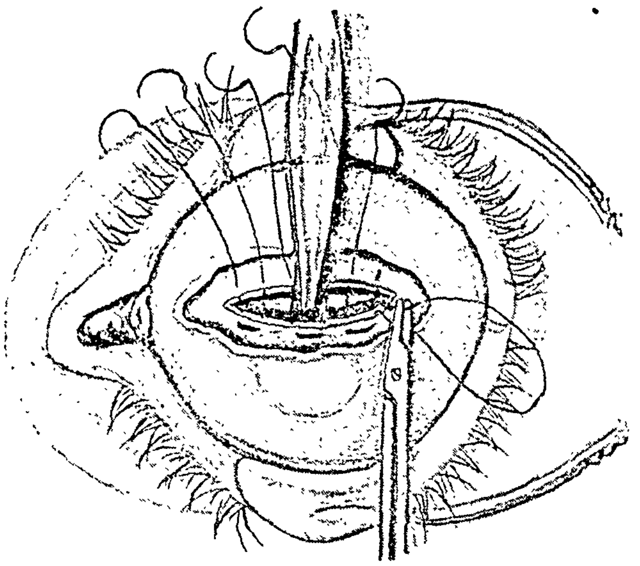

Fig. 2.—Compressor in scleral shell controls bleeding while sutures are being inserted.

The large ovoid compressor tip (for adults) or the smaller tip (for children) is introduced into Tenon's capsule immediately after the optic nerve is severed for enucleation or into the scleral shell after evisceration. Moderate constant pressure usually controls bleeding. The use of a compressor is more satisfactory for hematosis than is filling of the orbit or scleral shell with tampons and the use of digital pressure. Furthermore, with the use of tampons, the surgical procedure is necessarily halted

Aided by a grant from The Ophthalmological Foundation, Inc.

From the Department of Plastics, New York Eye and Ear Infirmary.

[2] The lucite® compressor described was made by R. O. Gulden, Philadelphia.

until the bleeding is stopped and the tampons removed from the orbit. In evisceration the scleral wound may be closed with the compressor in place (fig. 2), and the same is true of the suturing of Tenon's capsule in implantations following enucleation.

In several instances extrusion of an implant has been reported, which was apparently due to the fact that bleeding had not been adequately controlled before the implant was inserted. The compressor is of great assistance in controlling hemorrhage.

708 Park Ave.

COUNCIL ON PHARMACY AND CHEMISTRY

NEW AND NONOFFICIAL REMEDIES

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application.

R. T. Stormont, M.D., *Secretary.*

Cortisone Acetate (See New and Nonofficial Remedies 1952, p. 322).

Merck & Company, Inc., Rahway, N. J.

Ophthalmic Ointment Cortone Acetate: 3.5 gm. tubes. An ointment containing 15 mg. of cortisone acetate in each gram.

Ophthalmic Suspension Cortone Acetate 0.5%: 5 cc. dropper bottles. An isotonic, buffered solution containing 5 mg. of cortisone acetate in each gram. Preserved with 0.02% benzalkonium chloride.

Ophthalmic Suspension Cortone Acetate 2.5%: 5 cc. dropper bottles. An isotonic, buffered solution containing 25 mg. of cortisone acetate in each gram. Preserved with 0.02% benzalkonium chloride.

Tablets Cortone Acetate: 5 mg.

Heparin Sodium-U. S. P. (See New and Nonofficial Remedies 1952, p. 208).

Abbott Laboratories, North Chicago, Ill.

Solution Heparin Sodium: 10 cc. vials. A solution containing 5,000 U. S. P. units of heparin sodium in each cubic centimeter; 5 cc. vials. A solution containing 10,000 U. S. P. units of heparin sodium in each cubic centimeter. Preserved with 0.18% methylparaben and 0.02% propylparaben.

Aminophylline-U. S. P. (See New and Nonofficial Remedies 1952, p. 294).

The Bowman Bros. Drug Company, Canton, Ohio.

Tablets Aminophylline: 0.1 gm. plain and 0.2 gm. enteric coated.

Aureomycin Hydrochloride-U. S. P. (See New and Nonofficial Remedies 1952, p. 117).

Lederle Laboratories Division, American Cyanamid Company, Pearl River, N. Y.

Capsules Aureomycin Hydrochloride: 100 mg.

Methamphetamine Hydrochloride-U. S. P. (See New and Nonofficial Remedies 1952, p. 185).

Rexall Drug Company, Los Angeles.

Tablets Methamphetamine Hydrochloride: 2.5 mg. and 5 mg.

COUNCIL ON FOODS AND NUTRITION

Owing to the current interest in sodium-restricted diets, the Council on Foods and Nutrition has authorized the publication of the following article.

James R. Wilson, M.D., *Secretary.*

NUTRITIONAL IMPLICATIONS OF SODIUM RESTRICTION

In the preparation of diets restricted to less than 0.5 gm. of sodium daily, alterations from the diet usually considered optimum may be necessary. Thus, a reduction in animal protein and the nutrients usually associated with it may be required and certain other foods specifically prepared to remove naturally occurring sodium may be added to the diet. These alterations in the usual dietary customs of persons may sometimes compromise optimum nutrition, a matter to be seriously considered by physicians prescribing a low-sodium diet.

Such changes in the diet as the omission of salt for seasoning, using sweet butter, low-sodium bread, and omitting foods naturally high in sodium should involve no nutritional difficulties, except for any attendant decrease in taste appeal. The same is also true for processed foods packed without added sodium salts.

Limitations in the amount of meat and eggs allowed per day will sometimes be necessary, particularly if the daily sodium intake is to be 200 mg. or less. This involves a decrease in protein of high biological value and of the concomitant vitamins of the B complex.

The processing of foods to remove natural sodium may decrease the content of certain other nutrients. Products such as these are appearing on the market in increasing numbers and may be highly desirable because of the low levels of sodium they provide. At present, the extent of the reduction in nutrients other than sodium in these foods is not known, in many instances, but efforts will be made to procure this information and make it available to physicians.

Thus, the physician prescribing a low-sodium diet must weigh carefully the therapeutic benefits to be expected against the consequences of a possible reduction in the intake of essential nutrients. This may be particularly true of persons already malnourished or with conditioning factors such as defects in digestion and absorption or abnormalities in intermediary metabolism.

The Council will consider for acceptance foods packed or prepared without added sodium provided the food is otherwise acceptable and provided the sodium content appears on the label (in milligrams per 100 gm.) in addition to a statement such as "Packed without added sodium." The Council will also consider foods processed to remove naturally occurring sodium. When significant loss of nutrients, other than sodium, is shown to have occurred, a statement to this effect must also appear on the label and detailed information concerning this reduction in specific nutrients must be made available to the Council and to physicians likely to use the product.

ACCEPTED FOODS

The following product has been accepted as conforming to the rules of the Council.

James R. Wilson, M.D., *Secretary.*

B. M. Mishler Company, Pasadena, California.

Bradford Brand Dietetic Pack Tuna. Ingredients: Light meat tuna and distilled water.

Analysis (submitted by distributor).—Total solids 30.6%, moisture 69.4%, protein (N × 6.25) 28.3%, fat (ether extract) 0.75%, carbohydrates (by difference) 0.15%, sodium 40 mg./100 gm., cholesterol 70 mg./100 gm.

Calories.—1.22 per gram; 35 per ounce.

Use.—A useful adjunct for the planning of low fat, low sodium dietaries.

PREVENTION OF RABIES

The physician who treats a patient exposed to the bite or saliva of an animal is confronted now with a more difficult problem than in the past. Current developments in the field of rabies prophylaxis have led to conflicting opinions concerning the indications for the Pasteur treatment, the degree of efficacy of this form of treatment, and the incidence of postvaccinal neurological sequelae. In December, 1951, Koprowski and Cox [1] noted in a review that until recent years it was customary to give the Pasteur treatment to all persons exposed to the saliva of an animal that behaved abnormally. There has been a trend, however, toward greater conservatism in using the Pasteur treatment. Behind this change in attitude lie two major factors: the questionable value of the Pasteur treatment in cases in which severe wounds have been inflicted by obviously rabid animals, and the occurrence of a significant number of serious postvaccinal neurological sequelae.

Pait and Pearson,[2] using data collected in the county of Los Angeles for 1940 to 1946, report an incidence of neuroparalytic reactions of 1:600 among persons receiving Semple vaccine, while the chances of acquiring rabies following a known dog bite in the city of Los Angeles varied from 1:1400 to 1:2100. Similarly, in Manhattan among 3,305 patients who received the Pasteur treatment during the period 1946 to 1949, in 6 postvaccinal paralysis developed, an incidence of 1:551.[3] On the other hand, Sellers [4] found 7 cases of post-treatment paralysis among about 50,000 patients treated, an incidence of 1:7000. The exact incidence of these postvaccinal reactions is not known, but a significant number of neuroparalytic sequelae, including some fatalities, do occur. Thus in deciding whether to administer antirabies vaccine the physician must balance the risk of a potential serious postvaccinal reaction against the possibility of the development of rabies.

Indications for vaccine treatment in cases of animal bites were considered by the first session of the WHO Expert Committee on Rabies, held in April, 1950. The committee published [5] detailed indications for the use of vaccine treatment that are designed to avoid, as much as possible, indiscriminate use of the Pasteur treatment. Use of the Pasteur treatment was favored only in cases of bites and licks of uncaptured, wild, or rabid animals and in cases of multiple bites of the head, neck, and shoulders. Similar conservatism has been advocated by Sellers,[6] who considers antirabic treatment contraindicated in the following circumstances: (1) when there is no broken skin anywhere on the body, including face or mouth; (2) if previous wounds are known to be over 24 hours old or are covered with an unbroken scab; (3) if the tooth wounds were made through untorn clothing (such wounds are usually bruises); (4) if exposure is limited to handling only the dog or objects contaminated with the saliva, or to drinking the milk of rabid cows or goats; (5) if the wounds were inflicted not less than seven days prior to the detection of visible signs of the disease; and (6) if the animal remains normal for as long as seven days after inflicting the wounds. Reimmunization should be avoided for borderline exposure regardless of the time elapsed since the last treatment, according to Sellers. He recommends that re-treatment be limited in any case to a short booster series of five or six injections.

The use of antirabies serum, although known since 1889, has never gained prominence; however, since 1948, concentrates of antirabies serum prepared in sheep or rabbits have been available for clinical trial in the United States. The series of human patients treated with antirabies serum is not yet sufficiently large to draw definite conclusions, but Koprowski reports that no person who has received antiserum has died of rabies.[1] At the time of Koprowski's report,[1] in December, 1951, antiserum had been given to 48 persons. Of these, 29 were bitten by animals shown to be rabid. He recommended the administration of the serum as soon as possible after exposure, preferably within 24 hours. He used it in conjunction with vaccine, which may be administered 24 hours after administration of the antiserum, or possibly somewhat later, since rabies antibodies remain present for 7 to 10 days after passive immunization. Serum sickness was noted in about 20% of those treated with rabbit serum and in a much larger number of those treated with sheep serum. Therefore, the production of serum in sheep has been discontinued in favor of horse or rabbit serum. Although the usual precautions to be observed with the use of serums apply here, serum sickness would be less serious than rabies or a serious neuroparalytic complication. Antiserum is particularly suited for therapy of those patients with severe bites of the head or neck in which the Pasteur treatment has been least efficacious. If further clinical studies confirm the successful results obtained in experimental work [7] with the use of antiserum, it may be possible to reduce the number of injections of phenolized vaccine when antiserum is used adjunctively.[1] It should thus be possible to reduce the incidence of neurological sequelae, since it is known that paralytic complications occur more frequently when an increased number of injections of vaccine are given.

A recent departure from the presently used phenolized antirabies vaccine is the development of the chick-embryo-adapted Flury strain of live rabies virus vaccine.[8] This vaccine has been used widely and with apparent effectiveness in the immunization of dogs and gives promise of eliminating the postvaccinal neuroparalytic sequelae, which are thought by most investigators to be due to sensitization to brain tissue. A recent communication [9] from Israel reports that since the start of the antirabies campaign in October, 1950, carried on with the assistance of WHO, the number of rabies cases in animals has dropped from an average of 100 a year, before the start of the campaign, to 10 in the 15 months prior to the report. This program includes a mass vaccination of dogs with egg-adapted vaccine (Flury strain). There were no deaths in humans from rabies in Israel in 1951, whereas there were 20 such deaths between 1948 and 1950. Although it is too early to determine to what extent vaccine has brought about the decline in rabies incidence, it is believed that the mass vaccination has played an important part. The egg-adapted vaccine has proved harmless to dogs and seems to give a greater and longer immunity than other vaccines, according to this communication. This vaccine has also been administered to about 50 persons without undue reactions resulting.[10] It appears to offer possibilities for use in humans but further study of the problem is required.

[5] Expert Committee on Rabies: Report on the First Session, World Health Organization Technical Report Series, 3-17 (Nov.) 1950.

The ultimate solution to the problem of rabies in human beings is complete eradication of the disease in animals. It has been demonstrated that the disease may be controlled by mass vaccination in dogs and thus prevented in human beings when dogs are the sole source of infection. In view of the widespread geographic distribution of rabies and the many species of animals involved, however, complete eradication in animals is extremely difficult. Therefore, continued research to improve agents for prevention of this disease in exposed persons is indicated. Current developments in rabies prophylaxis, although they do not yet offer a final solution to the problem of rabies prevention, seem to justify an optimistic outlook for the future.

WHY MEDICAL GROUPS DISSOLVE

The Bureau of Medical Economic Research has recently published Bulletin 90, "Discontinuance of Medical Groups, 1940-1949." [1] Of the 441 medical groups in existence at the start of the 1940's, 82 were discontinued during the decade; of these 82, 40 were dissolved entirely, 27 were still in existence but had ceased to meet the requirements of the Bureau's definition of a group, and 15 were reorganized. By restricting their study to the groups that were discontinued and to the reasons therefor, the authors have avoided any discussion of the pros and cons of group practice, particularly from the standpoint of the patient. They have taken a leaf out of research publications in the field of marketing and have tried to set forth the reasons why some groups fall by the wayside, in the hope that such an analysis will be helpful to a physician who is contemplating organizing, joining, or reorganizing a medical group or choosing individual or nongroup partnership practice.

GRANTS BY NATIONAL FUND FOR MEDICAL EDUCATION PAST $2,500,000 MARK

With the awarding of its third series of grants to the medical schools this month, the National Fund for Medical Education has passed the $2,500,000 mark in the funds distributed to the medical schools in the past 12 months.

Included in this total is the $1,417,752 that has been raised by the American Medical Education Foundation to date. The important contributions of the medical profession to this nationwide program to raise funds for medical education has been formally recognized by the National Fund for Medical Education by the following resolution adopted unanimously by the Trustees of the fund at their last meeting.

"The Board of Trustees extend a vote of appreciation to the American Medical Association and the American Medical Education Foundation for the fine progress that they have made, and for their cooperation in turning over their collections to the Fund for distribution by it to the medical schools."

It is thus clear that the medical profession is setting an example of self-help that should stimulate industry and other groups in American society to make their contributions to this important undertaking.

The American Medical Education Foundation has set an annual goal of 2 million dollars to be raised by the medical profession. It is hoped that this goal can be reached for the first time during 1952. Prospects are reasonably good that this can be accomplished. Already 3,255 individual contributions have been received, which is 42.3% more than the total number of contributions received during the entire year 1951. Several state societies are just getting their campaigns into full operation. The Woman's Auxiliary, which has made two handsome contributions from its own funds, is embarking on an active campaign to: (1) stimulate gifts from individual physicians, (2) seek the financial support of over 1,000 auxiliaries, and (3) carry on a vigorous public education program on behalf of the Foundation.

When the medical profession achieves its goal of $2,000,000 annually the National Fund will be well on the way to its goal of raising $5,000,000 in unrestricted funds each year. When this has been accomplished, the more acute financial threats to the stability and continuing high quality of the medical schools should be substantially relieved. Physicians who have not yet contributed to the American Medical Education Foundation are urged to make their contributions promptly either through their state organizations or directly to the Foundation at 535 N. Dearborn Street, Chicago 10.

MEDICAL NEWS

CALIFORNIA

Discussion of the Normal Child.—The Southern California Society for Mental Hygiene on July 15 held a discussion at the Institute of Aeronautical Sciences in Los Angeles on guides to understanding the growth and development of the normal child. In addition to a community panel, the following physicians participated: Reynold A. Jensen, Minneapolis; Martha G. MacDonald, Palo Alto; C. Morley Sellery, Los Angeles; and Hale F. Shirley and Emmy Sylvester, San Francisco. Dr. Nathan K. Rickles of Beverly Hills, neuropsychiatric consultant, VA Hospital at Sawtelle, was moderator.

Personals.—Dr. Robert Wartenberg, clinical professor of neurology, University of California School of Medicine, San Francisco, has been elected an honorary member of the Italian Neurological Society.——Dr. John H. Aldes, Los Angeles, presented a paper entitled "The Use of Ultrasonic Therapy in the Treatment of Hypertrophic Arthritis with and Without Radiculitus—Geriatric Group" at the International Congress of Physical Medicine in London, England, July 14-19. He also attended the orthopedic association's meeting in London and planned to tour the rehabilitation centers in the Scandinavian countries before returning to the United States.

COLORADO

New Research Head at National Jewish Hospital.—Dr. Gardner Middlebrook, associate in the department of pathology and microbiology at the Rockefeller Institute for Medical Research in New York, has been appointed director of research and laboratories at the National Jewish Hospital in Denver to succeed Dr. Harry J. Corper, who has retired after 32 years of service as the institution's research head. The National Jewish Hospital, opened in 1899, is a nonsectarian tuberculosis center.

CONNECTICUT

Cerebral Palsy Study.—The cerebral palsy study conducted by the Connecticut State Department of Health in 1950 included determinations of the prevalence; the medical, social, psychological, and educational aspects; and the medical, educational, and institutional needs of cerebral palsy patients less than 21 years of age. The rates for children 5 to 9 and 10 to 14 years of age were much higher than for younger and older children. These differences in rates were considered to have been due to poor reporting or recognition of patients among infants and to the eventual adjustment to the diseases, favorable or unfavorable, among older persons. Specific needs of cerebral palsy patients were determined by detailed studies of sample groups of 130 Connecticut children. Less than half the Connecticut patients (34.3%) were considered as having potentialities for improving on an ambulatory system of therapy, and 51.7% of the children were recommended for inpatient care.

DISTRICT OF COLUMBIA

Freedmen's Hospital Interns and Residents.—At the annual session of the Association of Former Internes and Residents of Freedmen's Hospital, Dr. R. Frank Jones, professor of urology at Howard University College of Medicine, was elected president; Dr. Peyton R. Higginbotham, Bluefield, W. Va., president-elect; Dr. Charles R. Chephas, New Brighton, Pa., secretary; and Dr. L. Greeley Brown, Elizabeth, N. J., treasurer. The 31st session will be a memorial to Dr. William A. Warfield Sr., who was surgeon-in-chief of the hospital for 35 years.

ILLINOIS

Test for Insecticide Poisoning.—Testing of blood specimens for the detection of poison from exposure to insecticides is now offered by the diagnostic laboratories of the State Department of Public Health. This new service is made possible by the development in the department's laboratories of a specially prepared heparinized tube for collecting the blood samples. The special tubes may be had on request by physicians who need them for immediate use. Requests should be addressed to Howard J. Shaughnessy, Ph.D., Deputy Director in Charge of Laboratories, 1800 W. Fillmore St., Chicago 12.

The new test is for detection of poisoning with organic phosphates. As poisoning from such phosphates is cumulative, the test may be used best as a preventive, but it is helpful also in confirmation of diagnosis.

Chicago

Gift for Polio Research.—A check for $7,350 to further polio research was presented recently to Michael Reese Hospital by the Merton Davis Memorial Fund. This brings the total contributions of the Merton Davis Memorial Club to $24,450. This club was organized three years ago by a group of high school students in memory of a classmate who died of polio.

Dr. Frank Goes to North Carolina.—Dr. Edward Colman Frank has been appointed associate professor of psychiatry at the University of North Carolina School of Medicine, Chapel Hill, and will assume his new duties Sept. 1. Dr. Frank, who is adjunct psychiatrist at the Psychosomatic Institute of Michael Reese Hospital, is also consultant to Portal House Outpatient Clinic, Chicago; the Family Service Organization, Louisville, Ky.; and the alcoholic unit of the mental health centers of the state of Illinois. Dr. Frank was formerly psychiatrist for the David B. Rotman Research Laboratory of the Psychiatric Institute of the Municipal Court of Chicago.

Dr. Soskin Resigns as Director of Research Institute.—Dr. Samuel Soskin will resign as director of the Medical Research Institute of Michael Reese Hospital and dean of the hospital's postgraduate school, Sept. 1, to enter private practice in his specialty (diabetes and other metabolic and endocrine disorders) in Los Angeles. Dr. Soskin has been a full-time staff member of the hospital since 1929, when he was appointed director of metabolic and endocrine research, and from 1943 to 1950 he served as medical director of the institution. For 20 years he served first as assistant professor and later as professorial lecturer in physiology at the University of Chicago. Recently he has been an associate professor of medicine at Northwestern University Medical School. Dr. Soskin is a past president of the Chicago Society of Internal Medicine and of the Chicago Diabetes Association and a former chairman of the Illinois section of the Society for Experimental Biology and Medicine. He will continue as editor-in-chief of *Metabolism*, a scientific journal, and will devote time to research, teaching, and private practice.

INDIANA

Hospital Fund Drive.—Dr. Lawson J. Clark, Indianapolis, heads a 16 physician committee, which will serve among the physicians for the $12 million hospital fund drive. Pledges will be sought on a five year basis. The Hospital Development Association has already received in pledges a total of $1,400,000.

Anniversary of Medical Foundation.—An invitational open house followed by a dinner marked the 40th anniversary of the South Bend Medical Foundation, Inc. Dr. Alfred S. Giordano has been director of the foundation since 1922. Dr. Robert A. Moore, professor of pathology and dean of the school of medicine, Washington University School of Medicine, St. Louis, addressed the guests.

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education and public health. Programs should be received at least three weeks before the date of meeting.

NEW YORK

Dr. Simpson Honored.—Dr. Leo F. Simpson of Rochester was recently awarded an honorary degree of doctor of science by St. Bonaventure University as "an outstanding physician and surgeon who has won the universal admiration of colleagues, assistants, patients and the public." Dr. Simpson is a past president of the Monroe County Medical Society, the Rochester Academy of Medicine, and the Medical Society of the State of New York.

New York City

Society News.—The New York Roentgen Society announces election of the following officers: Dr. John L. Olpp, Tenafly, N. J., president; Dr. Irving Schwartz, vice-president; Dr. Harold W. Jacox, secretary; and Dr. Jacob R. Freid, treasurer.

Personals.—Dr. Norman H. Joliffe, director of the Bureau of Nutrition of the New York City Department of Health, was recently elected president of the National Vitamin Foundation, Inc., an industry-supported institution for financing research in nutritional fields.——Dr. H. Houston Merritt, professor of neurology at Columbia University College of Physicians and Surgeons, has been appointed to the advisory committee on virus research and epidemiology of the National Foundation for Infantile Paralysis.

Palsy Center Affiliates with Medical College.—Nassau County's new $500,000 Cerebral Palsy Diagnostic and Treatment Center, recently completed at Roosevelt, L. I., has become affiliated with New York Medical College, Flower-Fifth Avenue Hospitals. The affiliation will make available to the center the services of specialists and at the same time will provide training for medical students and physicians. Dr. Milton J. Wilson, professor of orthopedics, Dr. Lawrence B. Slobody, professor of pediatrics, and Dr. Robert V. Martin, director of the new center, will act with Dr. J. A. Werner Hetrick as an advisory committee. The new center, built through public contributions and with the assistance of local trade unions, which donated thousands of free man-hours of labor, went into full operation July 1. At capacity, it will provide outpatient treatment for 295 children with palsy at a time.

NORTH CAROLINA

Dr. Warren Joins Duke Faculty.—Dr. James V. Warren, president of the American Federation for Clinical Research, has been appointed professor of medicine at The Duke University School of Medicine, Durham. Formerly a professor of medicine and physiology at Emory University School of Medicine, Atlanta, Dr. Warren recently received a grant-in-aid from the American Heart Association for research in heart and blood diseases at Duke. In addition to his duties at Duke, he will help enlarge the medical department of the new Veterans Administration Hospital in Durham. Dr. Warren recently was given a brief leave of absence to serve on a U. S. Navy medical project in Africa.

OHIO

Research in Leukemia.—A foundation to support research in leukemia has been established at Ohio State University College of Medicine through a gift of $18,946 by Dr. and Mrs. James O. Beavis of Dayton, whose son, James Ewing Beavis, was a victim of the disease last summer.

Course in Heart Disease of Children.—A course in heart disease of children will be offered at the Cincinnati Children's Hospital and allied institutions Sept. 16-19. There will be opportunities for examination of patients and observation of new techniques of diagnosis. The course will be restricted to 10 physicians. A fee of $50 will be charged. For information, address the Children's Heart Association, 3231 Burnet Ave. (General Hospital), Cincinnati 29.

State Society Encourages Rural Practice.—The committee on rural health of the Ohio State Medical Association recently inaugurated a series of informal lectures to encourage senior medical students to take up the general practice of medicine as a career. The series of lectures was the culmination of several years of effort on the part of the committee to bring forth practical talks that would present the facts on rural medical practice.

Topics covered in the series included: "Selecting the Place to Practice"; "Type of Practice Encountered"; "Hospital Connections and Emergencies"; "The Economics of a Rural Practice"; and "The Physician and His Community." Dr. J. Martin Byers, Greenfield, chairman of the committee on rural health, and Dr. Edmond K. Yantes, Wilmington, a member of that committee and of the Committee on Medical Service Plans of the Association, served as volunteer lecturers. The committee will meet during the summer to plan with the Ohio State University medical faculty the program for next year. The possibilities of making similar arrangements with both of the other medical schools in the state will be explored.

WEST VIRGINIA

Dr. Kemper Retires as Health Officer.—Dr. Americus Kemper of Clarksburg retired July 1 as health officer for Harrison County after 21 years of service. On the day before his retirement, the staffs of the Harrison County Health Department and the Harrison tuberculosis office, and the school nurse presented him with a camera, and the Harrison County Medical Society gave him a gold watch at a banquet.

Personals.—Dr. David C. Prickett of Weston, health officer for district no. 4, has accepted appointment as director of the Marion County Health Department to succeed Dr. A. Glenn Evans, resigned.——Dr. Benjamin M. Drake of Charleston, deputy state director of health, has resigned to accept appointment as head of the division of preventive medical services of the Kentucky State Department of Health with headquarters in Louisville.——Dr. Frank J. Holroyd of Princeton, past president of the West Virginia State Medical Association, has been reappointed by Governor Patteson as a member of the medical licensing board for the term ending June 30, 1957.——Dr. Hu C. Myers of Philippi has been reappointed by Governor Patteson as a member of the advisory board of the hospital licensing program of the State Department of Health. His term will expire June 30, 1959.

GENERAL

Group Psychotherapy Seminars.—The Group Psychotherapy Institute, New York, has announced the addition of three seminars for the 1952-53 academic year, each to run for 30 consecutive two-hour sessions beginning October, 1952: (1) "Survey Seminar in Group Psychotherapy," (2) "Activity Group Therapy with Children," and (3) "Analytic Group Psychotherapy." Among the instructors will be Drs. Nathan W. Ackerman, Aaron Stein, James J. Thorpe, Joseph J. Geller, and Hyman Spotnitz, New York, and Samuel B. Hadden, Philadelphia. Information may be obtained from the Institute, 105 E. 22nd St., New York 10.

Research Fellowships.—The American College of Physicians announces that a limited number of fellowships in medicine, carrying a stipend of $3,000-$3,500, will be available from July 1, 1953 to June 30, 1954. The fellowships are designed to provide an opportunity for research training in the basic medical sciences or in the application of these sciences to clinical investigation. Assurance must be provided that the applicant will be acceptable in the laboratory or clinic of his choice and that he will be provided with the facilities necessary for the proper pursuit of his work. Application forms, supplied on request to the American College of Physicians, 4200 Pine St., Philadelphia 4, must be submitted in duplicate not later than Oct. 1.

Applications for Grants in Cancer Research.—The Committee on Growth of the National Research Council, acting for the American Cancer Society, is accepting applications for grants in support of cancer research. Applications for new grants received before Oct. 1 will be considered during the winter, and grants recommended at that time will become effective July 1, 1953. Investigators now receiving support will be notified individually regarding application for renewal of these grants. The research program includes, in addition to clinical investigations on cancer, fundamental studies in the fields of cellular physiology, morphogenesis, genetics, virology, biochemistry, metabolism, nutrition, cytochemistry, physics, radiobiology, chemotherapy, endocrinology, and environmental cancer. During the past year the American Cancer Society, on recommendation of the Committee on

Growth, has awarded approximately 250 grants totaling about $1,700,000. Application blanks may be obtained from the Executive Secretary, Committee on Growth, National Research Council, 2101 Constitution Ave., Washington 25, D. C.

Rocky Mountain Radiological Society Conference.—The annual Mid-Summer Conference of the Rocky Mountain Radiological Society will be held in Denver at the Shirley-Savoy Hotel Aug. 7-9. Dr. Philip J. Hodes, Philadelphia, will discuss the roentgen manifestations of (1) pancreatic and periampullary disease and (2) cerebellopontine angle tumors; Dr. Harold O. Peterson, St. Paul, will speak on the roentgen diagnosis of benign gastric ulcer and unusual neurological conditions with diagnostic roentgen findings; Dr. George H. Ramsey, Rochester, N. Y., will present cinefluorographic analysis of (1) some movements of the cervical spine and (2) the causes of dysphagia; and Dr. A. Justin Williams, San Francisco, will speak on the roentgen diagnosis of intra-abdominal hernia.

A symposium on diseases of animals transmissible to man will be presented. Evening meetings will include a joint session with the Denver Medical Society, followed by Dutch lunch, and an informal banquet. The annual picnic on Saturday afternoon will conclude the conference.

National Medical Association.—The National Medical Association, Inc., will meet in Chicago, Aug. 11-15, under the presidency of Dr. Joseph G. Gathings of Washington, D. C. Headquarters of the meeting will be at the DuSable High School, Wabash Ave. and 50th St. On Monday morning there will be a panel discussion on "The President's Committee on the Health Needs of the Nation." Tuesday afternoon "Late Syphilis" will be presented as a symposium and illustrated lecture. The Wednesday morning session will open with the annual Stubbs Lecture on "Interesting Lesions of the Gastrointestinal Tract" by Dr. Ellsworth E. Hasbrouck, Chicago. On Wednesday afternoon there will be symposiums on modern obstetrical procedures and leukorrhea. A symposium on gastritis will be held Thursday afternoon, and on Friday time will be given to psychiatric problems that confront the general practitioner. Another symposium, to be held at the same time, will deal with common fractures of the upper and lower extremities.

Photography in Medicine and Biology.—How to make photography serve more effectively in medicine and biology is the subject of a symposium at the Hotel New Yorker, New York. Aug. 12 as part of the convention of the Photographic Society of America. Among many others, Dr. David S. Ruhe of New York, director of the Audio-Visual Institute of the Association of American Medical Colleges, will speak on "The Changing Ideology of Medical Teaching Motion Pictures."

Techniques and equipment for the types of photography carried on in a general hospital will be described by Leonard A. Julin, of the Mayo Clinic, Rochester, Minn. Dr. Dan H. Gordon, professor of ophthalmologic surgery at Cornell University Medical College, will review the rapid advances in techniques for photographing the eye. Co-chairmen of the symposium are Dr. Milton G. Bohrod of Rochester, N. Y., General Hospital, and H. Lou Gibson of the Medical Division of Eastman Kodak Company. Registration fee for the day is $2. The Photographic Society of America has headquarters at 2005 Walnut St., Philadelphia 3.

Physical Medicine Congress.—The annual scientific session and instruction seminar of the American Congress of Physical Medicine will be held Aug. 25-29 at the Roosevelt Hotel, New York, under the presidency of Dr. Robert L. Bennett of Warm Springs, Ga. Lecturers for the instruction seminar include: Drs. Charles O. Bechtol, San Francisco; Robert L. Bennett, Warm Springs, Ga.; Frances A. Hellebrandt and Meyer A. Perlstein, Chicago; Frank H. Krusen, Rochester, Minn.; Allen S. Russek and Joseph D. Sullivan, New York; and Malford W. Thewlis, Wakefield, R. I. The charge for the eight lectures is $15.

On Monday there will be a luncheon of the Advisory Committee on Education, Council on Physical Medicine and Rehabilitation, American Medical Association. This will be followed by an educational conference, at which the following topics will be discussed: "University Sponsored Graduate Fellowship Training in the Medical Specialties," "Method of AMA Residency Approval," "Undergraduate Instruction in Physical Medicine and Rehabilitation," and "Report of the Advisory Committee of the Council on Physical Medicine and Rehabilitation of the American Medical Association." On Wednesday Dr. Frank H. Krusen, professor of physical medicine and rehabilitation, Mayo Foundation, will deliver the second John Stanley Coulter Memorial Lecture on "Report on the International Congress of Physical Medicine." Wednesday evening the annual congress dinner will be held.

On Thursday at 10 a. m. there will be a rehabilitation symposium, with the following presentations:

Howard A. Carter, M.E., Chicago, Rehabilitation of the Hard of Hearing.

Samuel S. Sverdlik, New York, Evaluation of Speech Training in the Rehabilitation of the Aphasic.

Everill W. Fowlks, Portland, Ore., Patient Evaluation by Wechsler Bellevue Test.

Charles H. Reagan, Tuscaloosa, Ala., Rehabilitation of 120 Lobotomized Patients in a VA Hospital.

Edith L. Kristeller, New York, Work Program for the Disabled Housewife.

Marion Strauss Lesser, M.A., and Robert C. Darling, New York, Some Follow-Up Studies in Rehabilitation at the Institute for the Crippled and Disabled.

Adam Peylan, Tel-Aviv, Israel, Combined Use of Hydrotherapy and Sweating Cure in Certain Arthritis Problems.

Heart Association Seeks Research Applicants.—New research applications in cardiovascular and related fields are being accepted by the American Heart Association for studies to be conducted during the year beginning July, 1953, according to Dr. Louis N. Katz, Chicago, chairman of the association's scientific council. Research fellowships are open to graduates of approved medical and graduate schools who are interested in research and who plan to follow an academic career. Established investigatorships are open to persons of proved ability who have the degree of Doctor of Medicine, Doctor of Philosophy, Doctor of Science, or the equivalent, and who are interested in a career in research. Grants-in-aid are available to nonprofit institutions for a specified program of research, including work in the basic sciences, under the direction of an experienced investigator.

The research committee recently voted to increase the stipends granted to research fellows and established investigators. Under the new scale, research fellowships, which are granted for a one year period, range from $3,500 to $5,500. Established investigatorships, which may be extended annually for a five year period, range from $6,000 to $9,000. Grants-in-aid are awarded in varying amounts, usually not exceeding $10,000, and the period covered is variable, depending on the particular program of study. Applications for research fellowships and established investigatorships should be submitted by Sept. 15. Applications for research grants-in-aid may be filed up to Dec. 1. Information may be obtained from the Medical Director, American Heart Association, 1775 Broadway, New York 19.

International Surgeons Meeting.—The annual assembly of the U. S. and Canadian chapters of the International College of Surgeons will take place at the Conrad Hilton Hotel in Chicago, Sept. 2-5. Dr. Henry W. Meyerding, Rochester, Minn., is president of the U. S. chapter and Dr. Lyon H. Appleby, Vancouver, B. C., president of the Canadian chapter. The assembly will open with a gallbladder symposium Tuesday morning. During the luncheon in the North Ballroom (11:45 a. m. to 1:45 p. m.), there will be a panel on the symposium, with Dr. Arnold S. Jackson of Madison as moderator. The Tuesday evening session will be devoted to a symposium on antibiotics. The clinic, Wednesday morning, will be followed by a roundtable discussion on treatment of duodenal ulcers, and the evening session will be devoted to a film forum. The Thursday morning program will feature recent developments in clinical research. During this session the Herbert Acuff Memorial Address on "Feasibility of Prolonged Survival Following Total Pelvic Exenteration for Advanced Cancer" will be delivered at 9 a. m. by Dr. Alexander Brunschwig, New York, and the Custis Lee Hall Memorial Address on "Volkman's Ischaemic Contraction" will be given at 10 a. m. by Dr. Meyerding. On Thursday at 4:10 p. m. there will be a roundtable discussion on surgery of the colon, rectum, and anal canal.

The speaker at the banquet, Thursday evening, is Mr. Arthur Dickson Wright, F.R.C.S., surgeon at St. Marys Hospital and

Prince of Wales Hospital, London, and a member of the council of the Royal College of Surgeons of England.

The convocation will be held at the Civic Opera House at 7 Friday evening. The Right Hon. Lord Horder, G.C.V.O., M.D., F.R.C.P., F.R.C.S., of London, England, will deliver an address on "Freedom in Medicine."

Two special features of the meeting will be the program on Tuesday of a new section devoted to the basic sciences allied to surgery, and a special program for operating room nurses.

Among the foreign surgeons who are expected to make presentations during the session are the following: Dr. Bernhard Zondek, head of the hormone research laboratory, Hadassah Medical School of the Hebrew University of Jerusalem; Dr. Raymond Darget, professor of urology at the University of Bordeaux; Dr. Lucien Leger, assistant professor of surgery, University of Paris; and Dr. Antonio Puigvert Gorro, director of the Institute of Urology, University of Barcelona.

Prevalence of Poliomyelitis.—According to the National Office of Vital Statistics, the following number of reported cases of poliomyelitis occurred in the United States and its territories and possessions in the weeks ended as indicated:

CORRECTION

Florida Medical Officers.—In The Journal, July 12, page 1038, Dr. Samuel M. Day, Jacksonville, was listed as editor of the *Journal of the Florida Medical Association.* Dr. Day was re-elected secretary-treasurer of the association, and Dr. Shaler A. Richardson, Jacksonville, was re-elected editor of the journal.

EXAMINATIONS AND LICENSURE

BOARDS OF MEDICAL EXAMINERS

Alabama: *Examination.* Montgomery, June 23-25. Sec., Dr. D. G. Gill, 537 Dexter Ave., Montgomery.

Alaska:* *Examination.* Juneau. On application in other towns where there are board members. *Reciprocity.* On application. Sec., Dr. W. M. Whitehead, Box 140, Juneau.

Arkansas:* *Examination.* Little Rock, Nov. 6-7. Sec., Dr. Joe Verser, Harrisburg.

California: *Written.* Los Angeles, Aug. 18-21; Sacramento, Oct. 20-23. Application must be received at least two weeks prior to date of examination. *Oral for Reciprocity Applicants.* Los Angeles, Aug. 16; San Francisco, Nov. 8. Applicants are requested not to arrange to come to an oral examination until they receive notice from the Credentials Committee. *Oral and Clinical for Foreign Medical School Graduates.* Los Angeles, Aug. 17; San Francisco, Nov. 9. Sec., Dr. Frederick N. Scatena, 1020 N St., Sacramento.

Colorado:* *Reciprocity.* Denver, Oct. 14. Exec. Sec., Mrs. B. H. Hudgens, 831 Republic Bldg., Denver.

District of Columbia:* *Reciprocity.* Washington, Sept. 8. Sec., Dr. Daniel L. Seckinger, 4130 E. Municipal Bldg., Washington.

Florida:* *Examination.* Jacksonville, Nov. 23-25. Sec., Dr. Homer L. Pearson, 701 Dupont Bldg., Miami 32.

Georgia: *Reciprocity.* Atlanta, Oct. 14-15. Sec., Mr. R. C. Coleman, 111 State Capitol, Atlanta 3.

Guam: The Commission on Licensure will meet whenever a candidate appears or submits his credentials. Ex. Sec., Dr. Austin W. Matthis, Agana.

Illinois: *Examination.* Chicago, Sept. 23-25. Supt. of Regis., Mr. Charles F. Kervin, Capitol Bldg., Springfield.

Kansas: Topeka, Dec. 10-11. Sec., Dr. O. W. Davidson, 864 New Brotherhood Bldg., Kansas City.

Michigan:* *Examination.* Lansing, Oct. 8-10. Sec., Dr. J. Earl McIntyre, 202-4 Hollister Bldg., Lansing.

Minnesota:* Minneapolis, Oct. 21-23. Sec., Dr. J. F. Du Bois, 230 Lowry Medical Arts Bldg., St. Paul 2.

Mississippi: *Reciprocity.* Jackson, December. Asst. Sec., Dr. R. N. Whitfield, State Board of Health, Jackson 113.

Montana: Helena, Oct. 6-8. Sec., Dr. S. A. Cooney, 214 Power Block, Helena.

Nebraska:* *Examination.* Omaha, June 1953. Director, Mr. Husted K. Watson, Room 1009 State Capitol Bldg., Lincoln 9.

Nevada:* Carson City, Aug. 4. Sec., Dr. George H. Ross, 112 Curry St., Carson City.

New Hampshire: Concord, Sept. 10. Sec., Dr. John S. Wheeler, 107 State House, Concord.

New Jersey: *Examination.* Trenton, Oct. 21-24. Sec., Dr. E. S. Hallinger, 28 W. State St., Trenton.

North Carolina: *Reciprocity.* Durham, Oct. 13. Sec., Dr. Joseph J. Combs, 419 Professional Bldg., Raleigh.

Ohio: *Reciprocity.* Columbus, Oct. 7. Sec., Dr. H. M. Platter, 21 W. Broad St., Columbus.

Oregon:* *Reciprocity.* Portland, July 25-26. Final date for filing application was June 16. Exec. Sec., Mr. Howard I. Bobbitt, 609 Failing Bldg., Portland.

South Carolina: *Reciprocity.* Columbia, Sept. 3. Sec., Mr. N. B. Heyward, 1329 Blanding St., Columbia.

Tennessee:* *Examination.* Memphis, Oct. 1-2. Sec., Dr. H. W. Qualls, 1635 Exchange Bldg., Memphis.

Texas: *Reciprocity.* Fort Worth, Aug. 3. Sec., Dr. M. H. Crabb, 1714 Medical Arts Bldg., Fort Worth.

Wyoming: Cheyenne, Oct. 6. Sec., Dr. Franklin D. Yoder, State Office Bldg., Cheyenne.

BOARDS OF EXAMINERS IN THE BASIC SCIENCES

Alaska: *Examination.* On application. Juneau or other towns in Territory as decided by Board. *Reciprocity.* On application. Sec., Dr. C. Earl Albrecht, Box 1931, Juneau.

Arizona: *Examination.* Tucson, Sept. 16. Sec., Mr. Herbert D. Rhodes, Room 423, Liberal Arts Bldg., University of Arizona, Tucson.

Arkansas: *Examination.* Little Rock, Oct. 1-2. Sec., Mr. Louis E. Gebauer, 1002 Donaghey Bldg., Little Rock.

Colorado: *Examination.* Denver, Sept. 10-11. Sec., Dr. Esther B. Starks, 1459 Ogden St., Denver 18.

District of Columbia: *Examination.* Washington, Oct. 20-21. Sec., Dr. Daniel L. Seckinger, 4130 E. Municipal Bldg., Washington.

Florida: *Examination.* Gainesville, Oct. 25. Sec., Mr. M. W. Emmel, Box 340, University of Florida, Gainesville.

Michigan: *Examination.* Detroit and Ann Arbor, Oct. 10-11. Sec., Mrs. Anne Baker, 423 W. Michigan Ave., Lansing.

Minnesota: *Examination.* Minneapolis, Oct. 7-8. Sec., Mr. Raymond N. Bieter, 105 Millard Hall, University of Minnesota, Minneapolis.

Nebraska: *Examination.* Omaha, Oct. 7-8. Director, Bureau of Examining Boards, Mr. Husted K. Watson, 1009 State Capitol Bldg., Lincoln.

New Mexico: *Examination.* Santa Fe, Sept. 21. Sec., Mrs. Marguerite Cantrell, Box 1592, Santa Fe.

Oklahoma: *Examination.* Oklahoma City, Sept. 13. Sec., Dr. Clinton Gallaher, 813 Braniff Bldg., Oklahoma City.

Oregon: *Examination.* Portland, Sept. 6 and Dec. 6. Sec., Dr. Charles D. Byrne, State Board of Higher Education, University of Oregon, Eugene.

Rhode Island: *Examination.* Providence, Aug. 13. Administrator of Professional Regulations, Mr. Thomas B. Casey, 366 State Office Bldg., Providence.

Texas: *Examination.* Austin, October. Sec., Brother Raphael Wilson, 407 Perry-Brooks Bldg., Austin.

Wisconsin: *Examination.* Madison, Sept. 13, Milwaukee, Dec. 6. Sec., Mr. W. H. Barber, 621 Ransom St., Ripon.

---

* Basic Science Certificate required.

MEETINGS

Alaska Territorial Medical Association, Anchorage, Aug. 21-23. Dr. William P. Blanton, P. O. Box 2569, Juneau, Secretary.

American Association of Obstetricians, Gynecologists and Abdominal Surgeons, The Homestead, Hot Springs, Va., Sept. 4-6. Dr. William F. Mengert, 2211 Oak Lawn Ave., Dallas, Texas, Secretary.

American College of Surgeons, Waldorf-Astoria, New York, Sept. 22-26. Dr. Michael L. Mason, 40 East Erie St., Chicago 11, Secretary.

American Congress of Physical Medicine, Roosevelt Hotel, New York, Aug. 25-29. Dr. Frances Baker, One Tilton Ave., San Mateo, Calif., Secretary.

American Hospital Association, Philadelphia, Sept. 15-18. Mr. George Bugbee, 18 East Division St., Chicago 10, Executive Director

American Medical Association Public Relations Institute, Edgewater Beach Hotel, Chicago, Sept. 4-5. Mr. Leo E. Brown, 535 N. Dearborn St., Chicago 10, Director.

American Physiological Society, New Orleans, Sept. 4-6. Dr. E. F. Adolph, University of Rochester School of Medicine and Dentistry, Rochester, N. Y., Secretary.

American Roentgen Ray Society, Shamrock Hotel, Houston, Texas, Sept. 23-26. Dr. Barton R. Young, Germantown Hospital, Philadelphia 44, Secretary.

American Society of Maxillofacial Surgeons, Hotel del Coronado, San Diego, Calif., Sept. 10-13. Dr. Casper M. Epsteen, 25 East Washington St., Chicago 2, Secretary.

Biological Photographic Association, Hotel New Yorker, New York, Sept. 10-12. Mr. Lloyd E. Varden, Pavelle Color, Inc., 533 W. 57th St., New York 19, Secretary.

Colorado State Medical Society, Stanley Hotel, Estes Park, Sept. 9-12. Mr. Harvey T. Sethman, 835 Republic Bldg., Denver 2, Executive Secretary.

Medical Society of Delaware, Rehoboth, Sept. 8-10. Dr. Andrew M. Gehret, 822 North American Bldg., Wilmington, Secretary.

Michigan State Medical Society, Book-Cadillac Hotel, Detroit, Sept. 24-26. Dr. L. Fernald Foster, 606 Townsend St., Lansing 15, Secretary.

Montana Medical Association, Florence Hotel, Missoula, Sept. 18-21. Mr. L. R. Hegland, 104 North Broadway, Billings, Executive Secretary.

National Medical Association, Chicago, Aug. 11-15. Dr. John T. Givens, 1108 Church St., Norfolk 10, Va., General Secretary.

Neurosurgical Society of America, The Cloister, Sea Island, Ga., Sept. 18-20. Dr. C. D. Hawkes, 22 North Manassas St., Memphis 5, Tenn., Secretary.

Nevada State Medical Association, Reno, Aug. 21-23. Dr. William A. O'Brien III, 505 Chestnut St., Reno, Secretary.

New Hampshire Medical Society, Mt. Washington Hotel, Bretton Woods, Sept. 7-9. Dr. Deering G. Smith, 44 Chester St., Nashua, Secretary.

North Pacific Pediatric Society, Challenger Inn, Sun Valley, Idaho, Sept. 19-20. Dr. S. Gorham Babson, 1107 S.W. 13th Ave., Portland 5, Ore., Secretary.

North Pacific Society of Internal Medicine, Sun Valley, Idaho, Sept. 19-20. Dr. Robert L. King, 1115 Terry Ave., Seattle 1, Wash., Secretary.

North Texas-Southern Oklahoma Fall Clinical Conference, Wichita Falls, Texas, Sept. 17. Dr. E. Aubrey Cox, Hamilton Bldg., Wichita Falls, Texas, Chairman.

Reno Surgical Society Conference, Reno, Nevada, Aug. 21-23. Dr. Olin C. Moulton, 130 N. Virginia St., Reno, Nevada, Chairman.

Rocky Mountain Radiological Society, Denver, Aug. 7-9. Dr. Maurice D. Frazer, 1037 Stuart Bldg., Lincoln, Neb., Secretary.

U. S. Chapter, International College of Surgeons, Conrad Hilton Hotel, Chicago, Sept. 2-5. Dr. Arnold S. Jackson, 1516 Lake Shore Drive, Chicago, Executive Secretary.

Utah State Medical Association, Salt Lake City, Sept. 4-6. Dr. T. C. Weggeland, 42 S. Fifth East St., Salt Lake City, Secretary.

Vermont State Medical Society, Mt. Washington Hotel, Bretton Woods, N. H., Sept. 7-9. Dr. James P. Hammond, 128 Merchants Row, Rutland, Secretary.

Washington State Medical Association, Olympic Hotel, Seattle, Sept. 13-17. Dr. Bruce Zimmerman, 338 White-Henry-Stuart Bldg., Seattle, Secretary.

European Congress of Cardiology. University of London, Bloomsbury, W.C.1, England, Sept. 10-12. Dr. K. Shirley Smith, 35 Wimpole St., London, W.1, England, Secretary.

European Society of Cardiovascular Surgery, Strasbourg, France, Oct. 3-4. Sir James Learmonth, Department of Surgery, University New Buildings, Edinburgh 8, Scotland.

Interamerican Cardiological Congress, Buenos Aires, Argentina, Aug. 31-Sept. 7. Dr. Blas Moia, Larrea 1132, Buenos Aires, Argentina, Secretary-General.

Inter-American Congress of Public Health, Havana, Cuba. Sept. 26-Oct. 1. Pan-American Sanitary Bureau, 2001 Connecticut Ave., Washington, D. C.

Inter-American Congress of Radiology, Mexico City, Mexico, Nov. 2-8. Dr. Guido Torres Martinez, Marsella No. 11, Mexico, D.F., Secretary-General.

International Congress of Anthropology and Ethnology, Vienna, Austria, Sept. 1-8. For information write: Secretaries, Royal Anthropological Institute, 52 Upper Bedford Place, London, W.C.1, England.

International Congress on Diseases of the Chest, Rio de Janeiro, Brazil, Aug. 24-30. Mr. Murray Kornfeld, 112 East Chestnut St., Chicago 11, Illinois, Executive Secretary.

International Congress of Haematology, Mar del Plata, Argentina, Sept. 21-26. Dr. Carlos Reussi, Anchorena 1710, Buenos Aires, Argentina, Secretary.

International Congress of the History of Medicine, Nice-Cannes, France, and Monaco, Sept. 8-14. Dr. F. A. Sondervorst, 124 Avenue des Allies, Louvain, Belgium, Secretary-General.

International Congress on Hydatid Disease, Santiago, Chile, Nov. 21-24. Organizing Committee, P. O. Box 9183, Santiago, Chile.

International Congress of Internal Medicine, Friends House, London, N.W.1, Eng. Sept. 15-18. Sir Harold Boldero, 12 Pall Mall East, London, S.W.1, England, Secretary.

International Congress of Medical Press, Venice, Italy, Oct. 4-5. Dr Bruno de Biasio, S. Marco 4646, Venice, Italy, Secretary.

International Congress on Medical Records, London, England, Sept. 7-12. Miss Gwen Perkins, 120 C Street S.E., Washington, D. C., Chairman.

International Congress of Military Medicine and Pharmacy, Montevideo, Uruguay, March 1-7, 1953. Dirreccion General del Servico de Sanitad Militar, 8 de Octubre y Mariano Moreno, Montevideo, Uruguay, Secretariat of the Congress.

International Congress on Neuropathology, Rome, Italy, Sept. 8-13. Dr. Armando Ferraro, 722 W. 168th St., New York, N. Y., U. S. A., Secretary General.

International Congress of Otorhinolaryngology, Amsterdam, Netherlands, June 8-15, 1953. Dr. W. H. Struben, J. J. Viottastraat 1, Amsterdam, Netherlands, Secretary.

International Congress of Therapeutics, Madrid, Spain, Oct. 16-18. Professor Armijo, Instituto de Farmacologia, Cuidad Universitaria, Madrid, Spain, Secretary.

International Congress of Urology, The Waldorf-Astoria, New York, N. Y., U. S. A., Sept. 15-18. Dr. John A. Taylor, 2 East 54th St., New York, N. Y., U. S. A., Secretary-General.

International Hospital Congress, London, England, May 25-30, 1953. Capt. J. E. Stone, 10 Old Jewry, London, EC2, England, Hon. Secretary.

International Study Conference on Child Welfare, Bombay, India, Dec. 5-12. For information write: All India Save the Children Committee, 5 Carmichael Road, Bombay, India.

International Union Against Tuberculosis, Rio de Janeiro, Brazil, Aug. 24-27. Prof. Etienne Bernard, 66 Blvd. St. Michel, Paris 6e, France, Secretary-General.

Medical Women's International Association, Vichy, France, Sept. 12-16. Dr. Margaret M. Wurts, 27 East Wellesley Road, Montclair, N. J., U. S. A., National Secretary.

Neuroradiologic Symposium, Stockholm, Sweden, Sept. 17-20. Docen Ake Lindbom, Symposium Neuroradiologicum, Serafimerlasarettet, Stockholm K., Sweden, Secretary.

World Congress of Jewish Physicians, Jerusalem, Israel, Aug. 10-14 Secretariat: % Israel Medical Association, Rehov Mesilat Yesharim Beth Kovatz, Jerusalem, Israel.

World Congress of Medicine, Montecatini, Italy, Oct. 16-18. Secretariat: Corso Trieste, 65, Rome, Italy.

World Federation of Mental Health, Brussels, Belgium, Aug. 25 Sept. 1. Dr. J. R. Rees, 19 Manchester St., London, W.1, Englanc Secretary.

World Medical Association, Athens, Greece, Oct. 12-16. Dr. Louis Bauer, 2 East 103d St., New York 29, N. Y., Secretary General.

DEATHS

Beck, Carl ⊕ Sayre, Pa.; born in Milin, Austria, March 26, 1864; Deutsche Universität Medizinische Fakultät, Prague, Austria, 1889; at one time assistant in surgery and gynecology in the clinics at Prague; made several trips to America as steamer surgeon in 1889-1890, settling in Chicago in the latter year to follow the general practice of medicine; served as volunteer in the 11th Infantry Regiment, Austrian Army, and later first lieutenant of the 75th Infantry Regiment; member of the military council and teacher of plastic surgery to military surgeons during World War I; for many years professor of surgical pathology and clinical pathology at the University of Illinois College of Medicine; formerly professor of surgery at the Post Graduate Hospital and Medical School and the Chicago College of Dentistry; fellow and a founder of the American College of Surgeons; past president of the Chicago Surgical Society; a founder of the German Medical Society and the Bohemian Medical Society of Chicago; member of the Illinois State Medical Society, German Society of Surgeons of Berlin, Society of Physicians of Prague, and the Royal Academy of Rome; founder and chief of staff of surgery, North Chicago Hospital; founded St. Anthony Hospital, with Sisters of Joliet; and was attending surgeon at Cook County and St. Joseph hospitals; originator of bismuth paste treatment for chronic sinusitis under name of Beck's paste; author of "Principles of Surgery," 1905, and "Crippled Hand and Arm," 1925, as well as of many articles in medical journals; died July 21, aged 88.

Brodhead, George Livingston ⊕ New York; born in New Orleans Oct. 14, 1869; College of Physicians and Surgeons, medical department of Columbia College, New York, 1891; an Associate Fellow of the American Medical Association; past president of the Medical Association of the Greater City of New York; member of the New York Academy of Medicine and New York Obstetrical Society; specialist certified by the American Board of Obstetrics and Gynecology; instructor in obstetrics at his alma mater from 1895 to 1897 and the New York University and Bellevue Hospital Medical College from 1899 to 1917; professor of obstetrics at the New York Post Graduate Medical School and Hospital from 1899 to 1916; served on the staff of St. Luke's Hospital in Newburgh, Letchworth Village in Thiells, United Hospital in Port Chester, Jamaica (N. Y.) Hospital, St. Agnes Hospital in White Plains, and Knickerbocker, Jewish Maternity, Lutheran, Union, and Bronx Maternity hospitals all in New York; author of "Approaching Motherhood"; died May 13, aged 82, of bronchopneumonia.

Kemper, John Willard ⊕ Ann Arbor, Mich.; born in Richmond, Ind., Sept. 14, 1891; University of Michigan School of Dentistry in Ann Arbor in 1917 and University of Michigan Medical School in 1927; joined the university staff as instructor in oral surgery in 1929; the following year became assistant professor, and in 1934 was elevated to the rank of associate professor; promoted to full professorship in 1935, and in the same year became head of the department of oral surgery and consulting dental surgeon to the University Hospital; for many years affiliated with St. Joseph's Mercy Hospital; specialist certified by the American Board of Plastic Surgery; fellow of the American College of Surgeons; first vice-president and second president of the American Society of Maxillofacial Surgeons; served during World War I; associate editor of the *American Journal of Orthodontics and Oral Surgery*; died in the University Hospital May 8, aged 60, of dissecting aneurysm of the aorta with cardiac tamponade.

Jones, Marvin Fisher ⊕ New York; born in Spencer, N. Y., March 10, 1889; University of Buffalo School of Medicine, 1913; specialist certified by the American Board of Otolaryngology; at one time on the faculty of New York Post Graduate Medical School of the New York University-Bellevue Medical Center; served in France during World War I; member of the American Academy of Ophthalmology and Otolaryngology, American Laryngological Association, American Ophthalmological Society, and the American Otological Society; fellow of the American College of Surgeons; consultant, Fitkin Memorial Hospital in Neptune, N. J., Tioga County General Hospital in Waverly, New York Hospital of New York, and United Hospital in Port Chester; since 1936 surgeon-director, department of otolaryngology at Manhattan Eye, Ear and Throat Hospital, where he was in charge of its conservation of hearing service, and where he died May 26, aged 63, of multiple myeloma and cardiac failure.

Gillick, David Walter ⊕ Talihina, Okla.; born in St. Louis, Aug. 9, 1895; St. Louis College of Physicians and Surgeons, 1919; fellow of the American College of Physicians; since Sept. 21, 1921, physician in the Indian Service, Department of Interior; medical officer in charge of Talihina Indian Medical Center, and during 1951-1952 was designated acting area medical officer for Eastern Oklahoma; served as superintendent and physician in charge of Shawnee Indian Sanatorium in Shawnee, and as district medical director of states, including Oklahoma, Kansas, Mississippi, North Carolina, and Florida; died in Muskogee March 29, aged 56, of cerebral hemorrhage.

Reeves, Thaddeus Benjamin ⊕ Greenville, S. C.; University of Virginia Department of Medicine, Charlottesville, 1914; member of the founders group of the American Board of Surgery; for two years instructor in anatomy at his alma mater; member of the Southern Surgical Association and the Alumni Association of the Mayo Foundation; fellow of the American College of Surgeons; formerly fellow in surgery at Mayo Foundation, Rochester, Minn.; attending surgeon at the Greenville General Hospital and the St. Francis Hospital; consulting surgeon at the Shriners Hospital for Crippled Children; orthopedic surgeon for the Southern Railway and the Piedmont and Northern Railway; died June 9, aged 66.

Carlisle, Chester Lee, Palo Alto, Calif.; Western Reserve University Medical Department, Cleveland, 1898; specialist certified by the American Board of Psychiatry and Neurology; member of the American Psychiatric Association and the Association for Research in Nervous and Mental Diseases; retired in July, 1946, after 15 years as clinical director of the Veterans Administration Hospital; served in state and federal hospitals for a period of 45 years; a captain in the medical corps of the U. S. Army during World War I; chief of division of mental defect and delinquency, New York State Board of Charities, from 1917 to 1920; formerly connected with the U. S. Public Health Service; died April 29, aged 75.

Kennedy, William Aloysius ⊕ St. Paul; born in Minneapolis Aug. 1, 1893; University of Minnesota Medical School, Minneapolis, 1918; member of the American Academy of Ophthalmology and Otolaryngology; specialist certified by the American Board of Ophthalmology; formerly secretary-treasurer of the Minnesota Academy of Ophthalmology and Otolaryngology; served during World War I; at one time a fellow in ophthalmology at Mayo Foundation; affiliated with Children's Hospital, Gillette State Hospital, and St. Joseph's Hospital, where he died April 30, aged 58, of right amyotrophic lateral sclerosis, cerebral hemorrhage, and terminal pneumonia.

Urie, James William ⊕ Wilmington, Del.; Hahnemann Medical College and Hospital of Philadelphia, 1929; served on Leyte and Luzon in the Philippines during World War II; during the campaign on Luzon was awarded the Bronze Star for heroic action in rescuing several wounded men; physician to Conrad High School football teams, and in 1950 health officer for the Memorial Hospital, where he served as secretary to hospital medical staff, and registrar for its school of nursing; affiliated with Wilmington General Hospital; died April 17, aged 46, of acute coronary thrombosis.

⊕ Indicates Member of the American Medical Association.

Beer, James Anderson ⊕ Columbus, Ohio; Ohio Medical University, Columbus, 1906; formerly assistant professor, university health service, Ohio State University College of Medicine; for many years city bacteriologist and at one time city health commissioner; served as treasurer of the Ohio State Medical Association; member of the American Association for the Advancement of Science; honorary member of the Columbus Academy of Medicine; died in White Cross Hospital April 30, aged 72, of cerebral hemorrhage.

Betts, George Seymour ⊕ Banner, Ill.; Medical Department of Omaha University, 1898; died April 27, aged 82, of heart disease.

Breese, Floyd Pinckney ⊕ Elmira, N. Y.; University of Buffalo School of Medicine, 1915; fellow of the American College of Surgeons; served during World War I; member of the honorary staff of the Arnot-Ogden Hospital; died in Coral Gables, Fla., March 16, aged 58, of acute myocardial infarction.

Brewer, Asbury Manton, Tunnel Hill, Ga.; Chattanooga (Tenn.) Medical College, 1901; died April 24, aged 79, of myocardial failure and hypertension.

Bunch, Morrell McKinsey, Muncie, Ind.; Bennett Medical College, Chicago, 1911; died April 25, aged 63.

Byram, James Waldamor, Willmar, Minn.; University of Minnesota Medical School, Minneapolis, 1931; affiliated with Willmar State Hospital; formerly affiliated with Hastings (Minn.) State Hospital; at one time a surgeon in the police department of St. Paul; died in Northwestern Hospital, Minneapolis, April 28, aged 49.

Charpentier, Albert Arthur, St. Paul; School of Medicine and Surgery of Montreal, Canada, 1899; died in Ancker Hospital April 12, aged 78, of coronary occlusion.

Creighton, Samuel Smith ⊕ Colonel, U. S. Army, retired, Cambridge, Md.; University of Buffalo School of Medicine, 1909; Army Medical School, 1911; entered the medical corps of the U. S. Army in 1911, and retired Dec. 31, 1939; fellow of the American College of Surgeons; died April 3, aged 71.

Daniels, Henry Manford, Venango, Pa.; Jefferson Medical College of Philadelphia, 1887; died recently, aged 92, of uremia and arteriosclerosis.

Dimm, Charles Hill ⊕ Mifflinburg, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1889; during World War I chairman of the Union County Draft Board and served as its medical examiner; died in George F. Geisinger Memorial Hospital, Danville, April 24, aged 88, of arteriosclerotic heart disease and prostatic hypertrophy.

Feldaker, Lipa M. B., St. Louis; University of St. Vladimira Faculty of Medicine, Kiev, Russia, 1922; died April 20, aged 68.

Fish, Julia F., Erie, Pa.; Pulte Medical College, Homeopathic, Cincinnati, 1901; died in Cambridge Springs, April 26, aged 86, of chronic arteriosclerotic heart disease.

Grant, John Henry, Tyler, Texas (licensed in Texas by years of practice); formerly practiced in Corpus Christi, and in 1918 was president of the Nueces County Medical Society; died April 19, aged 88.

Harris, John Simpson, McMinnville, Tenn.; University of Nashville Medical Department, 1894; Vanderbilt University School of Medicine, Nashville, 1894; died in the Vanderbilt University Hospital, Nashville, April 25, aged 84, of undiagnosed disease of biliary system with jaundice.

Harrison, Hugh ⊕ Detroit; Michigan College of Medicine and Surgery, Detroit, 1896; served on the staffs of Harper and St. Joseph Mercy hospitals; died April 27, aged 80, of arteriosclerotic heart disease.

Hazen, Charles Morse, Bon Air, Va.; Medical College of Virginia, Richmond, 1897; emeritus professor of physiology at his alma mater; died April 22, aged 86, of cancer.

Heid, George Joseph ⊕ Bushkill, Pa.; Western Pennsylvania Medical College, Pittsburgh, 1906; died April 5, aged 67.

Hennemeyer, Rudolph J. ⊕ Chicago; Friedrich-Wilhelms-Universität Medizinische Fakultät, Berlin, 1923; affiliated with Woodlawn Hospital; died in the Albert Merritt Billings Hospital May 23, aged 56, of malignant hypertension.

Hottenstein, Daniel Edgar ⊕ Millersburg, Pa.; University of Pennsylvania Department of Medicine, Philadelphia, 1903; past president of the Dauphin County Medical Society; for many years county medical director; died in Harrisburg (Pa.) Hospital April 30, aged 76, of pulmonary embolism and bronchopneumonia.

Huckaby, A. H., Griffin, Ga.; University of Georgia School of Medicine, Augusta, 1905; died March 18, aged 69, of mesenteric thrombosis.

Hudnutt, Orrin Dean ⊕ Plainwell, Mich.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1910; member of the Radiological Society of North America; past president of the Allegan County Medical Society; served during World War I; died in William Crispe Hospital April 25, aged 71.

Hurley, William Cyril Rowe ⊕ Sunapee, N. H.; Tufts College Medical School, Boston, 1916; member of the Massachusetts Medical Society; fellow of the American College of Surgeons; for many years practiced in Quincy, Mass., where he was affiliated with Quincy Hospital; died in Sarasota, Fla., April 26, aged 63, of dissecting aortic aneurysm and coronary artery disease.

Hyde, Allan Pearson ⊕ Sharon, Pa.; Cleveland Homeopathic Medical College, 1901; specialist certified by the American Board of Radiology; member of the Radiological Society of North America and the American College of Radiology; served during World War I; affiliated with Sharon General Hospital; a director of the First National Bank in Sharpsville; died April 30, aged 73, of coronary thrombosis.

Jones, Henry ⊕ Coolidge, Ga. (licensed in Georgia in 1895); director of Moultrie Banking Company; affiliated with Vereen Memorial Hospital in Moultrie, where he died April 30, aged 82, of heart disease.

McNamee, John Ellis, Madison, S. D.; Barnes Medical College, St. Louis, 1902; died April 1, aged 85, of hypertensive heart disease.

Matzke, Samuel E., Warsaw, Ill.; Kansas City (Mo.) Homeopathic Medical College, 1897; affiliated with St. Joseph's and Graham hospitals in Keokuk, Iowa, and Memorial Hospital in Carthage, where he died April 2, aged 79, of carcinoma.

Moore, William Lee ⊕ Madisonville, Ky.; Barnes Medical College, St. Louis, 1896; physician for the Louisville and Nashville Railroad and Illinois Central Railroad; member of the city council, 1950-1951; for many years member of the county board of health; on the staff of the Hopkins County Hospital; died recently, aged 85.

Mueller, Walter Edmund, Green Bay, Wis.; University of Illinois College of Medicine, Chicago, 1914; past president of the Brown-Kewaunee-Door Counties Medical Society; served during World War I; president of the medical staff of Bellin Memorial Hospital for many years; affiliated with Veterans Ad- ministration; died April 23, aged 61, of cirrhosis of the liver and coronary occlusion.

Murawsky, William Joseph ⊕ Burlington, Wis.; Marquette University School of Medicine, Milwaukee, 1929; member of the American Academy of General Practice; health officer of Lyons; affiliated with Burlington Memorial Hospital, where he died April 23, aged 47, of cerebral hemorrhage.

Murphey, Eugene Edmund ⊕ Augusta, Ga.; University of Georgia School of Medicine, Augusta, 1898; past president of the Medical Association of Georgia; fellow of the American College of Physicians; professor emeritus of clinical medicine at his alma mater; served during World War I; for many years chairman of the board of health, and city health officer; an associate member of the American Ornithologists Union; died April 13, aged 76, of pneumonia.

Nichols, James Lutellus ⊕ Alligator, Miss.; Vanderbilt University School of Medicine, Nashville, Tenn., 1911; twice president of the Clarksdale and Six Counties Medical Society; served in France during World War I; died in the Kennedy General Hospital, Memphis, Tenn., April 28, aged 65, of cerebral hemorrhage.

Phillips, Floyd C. ⊕ Arthur, Ill.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1902; also a graduate in pharmacy; served as president of the Douglas County Medical Society; died April 13, aged 74, of cardiorenal vascular disease.

Pieroth, John Philip, Seattle; Rush Medical College, Chicago, 1925; served during World War I; on the staff of the Virginia Mason Hospital; died April 14, aged 57, of pontine hemorrhage.

Piper, Clark Culbertson ⊕ Highland Park, Mich.; Rush Medical College, Chicago, 1915; died in Highland Park General Hospital April 22, aged 65.

Portoghese, Nunzio, San Diego, Calif.; Regia Università degli Studi di Palermo. Facoltá di Medicina e Chirurgia, Italy, 1906; died April 11, aged 73, of coronary occlusion.

Price, Nathaniel Gordon ⊕ Newark, N. J.; Bellevue Hospital Medical College, New York, 1897; served on the staff of Beth Israel Hospital; died in Daytona Beach, Fla., April 22, aged 75, of coronary occlusion.

Quirk, Frank John, Chicago; Bennett College of Eclectic Medicine and Surgery, Chicago, 1895; served during World War I; died in Wesley Memorial Hospital April 15, aged 82, of uremia and carcinoma of the prostate.

Ragsdale, Harrison Curtis ⊕ Bedford, Ind.; Indiana University School of Medicine, Indianapolis, 1920; fellow of the American College of Surgeons; served during World War II; affiliated with Veterans Administration Hospital in Dwight, Ill.; formerly on the staff of Dunn Memorial Hospital; died in Indianapolis April 26, aged 56.

Reichbaum, Theodore ⊕ Easton, Pa.; Harvard Medical School, Boston, 1925; specialist certified by the American Board of Internal Medicine; from 1929 to 1940 coroner of Northampton County; served during World War I; on the staff of Easton Hospital; died April 16, aged 55, of acute coronary thrombosis.

Rymer, Thomas Edward, Ripley, W. Va.; Starling Medical College, Columbus, 1903; for many years a member and president of the county board of education; served during World War I; died April 6, aged 76, of heart disease.

Simmons, Colon L., Hazlehurst, Miss.; Memphis (Tenn.) Hospital Medical College, 1900; past president of the Tri-County Medical Society; served as medical adviser for Selective Service during World War II; for a number of terms member of the board of aldermen of the city of Hazlehurst; on the staff of Hardy Wilson Memorial Hospital; died April 10, aged 75, of Hodgkin's disease.

Simpson, James Asa, Dallas, Texas; Vanderbilt University School of Medicine, Nashville, Tenn., 1900; fellow of the International College of Surgeons; member of the Industrial Medical Association; actively identified in National Guard units for many years; served in the Philippine Insurrection, the Spanish-American War, the Mexican Border campaign, and in France during World War I; affiliated with the War Relocation Authority in Topaz, Utah, during World War II; died April 20, aged 78, of coronary disease.

Sinkler, Samuel, Chicago; Chicago College of Medicine and Surgery, 1908; also a dentist; died in the Albert Merritt Billings Hospital April 25, aged 74, of hydronephrosis and bronchopneumonia.

Smith, French Miles ⊕ Lyndon, Kan.; University Medical College of Kansas City, Mo., 1909; secretary of the Osage County Medical Society; died in Kansas City, Kan., April 19, aged 73, of carcinoma of the pancreas.

Starks, John Charles ⊕ Gower, Mo.; Missouri Medical College, St. Louis, 1897; an Associate Fellow of the American Medical Association; died March 21, aged 77, of coronary occlusion and arteriosclerosis.

Stein, Frederick ⊕ Lyndhurst, N. J.; L.R.C.P., Edinburgh, L.R.C.S., Edinburgh, and L.R.F.P. & S., Glasgow, 1941; associate dermatologist, St. Mary's Hospital in Passaic; died April 21, aged 40, of coronary occlusion.

Stine, Harvey Andrew ⊕ Harrisburg, Pa.; Baltimore Medical College, 1912; consultant in obstetrics, Harrisburg Polyclinic Hospital; died April 4, aged 73, of myocardial infarction and arteriosclerosis.

Van Doren, Raymond Fleming ⊕ East Lynn, Ill.; Northwestern University Medical School, Chicago, 1911; an Associate Fellow of the American Medical Association; died May 5, aged 65, of cardiorenal disease.

Van Gundy, Clyde Rogers ⊕ Detroit; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1912; served overseas during World War I; on the staff of the Lincoln Hospital; died May 5, aged 65, of coronary thrombosis.

Vella, Salvatore I., Chicago; Chicago College of Medicine and Surgery, 1915; died in St. Luke's Hospital April 22, aged 64, of cerebral thrombosis, hypertension, and diabetes mellitus.

Vincil, Frank Hendricks, Portland, Ore.; Barnes Medical College, St. Louis, 1903; served during World War I; died in Veterans Administration Hospital April 30, aged 72, of coronary sclerosis and diabetes mellitus.

Vinson, Charles Samuel ⊕ Columbus, Ohio; Ohio State University College of Medicine, Columbus, 1941; served overseas during World War II; resident in radiology at Ohio State University Hospital, where he died April 28, aged 35, of coronary infarction.

Vogt, Elkin ⊕ Lithonia, Ga.; University of Georgia School of Medicine, Augusta, 1939; member of the American Academy of General Practice; died May 5, aged 49, of coronary thrombosis.

Wagner, Louise Dorothy ⊕ Santa Barbara, Calif.; Rush Medical College, Chicago, 1920; for many years practiced in Pasadena, where she was affiliated with Huntington Memorial Hospital; died in Santa Barbara Cottage Hospital April 2, aged 56, of carcinoma of the sigmoid.

Wagner, Nicholas Bacon, Platteville, Wis.; Rush Medical College, Chicago, 1910; died May 19, aged 73.

Wentz, Frank Riegel ⊕ Allentown, Pa.; Jefferson Medical College of Philadelphia, 1913; affiliated with Sacred Heart Hospital, where he died April 25, aged 60, of myocardial infarction.

Whelan, Joseph David ⊕ Manchester, N. H.; Georgetown University School of Medicine, Washington, D. C., 1934; served during World War II; chief of staff, Sacred Heart Hospital; died in the Veterans Administration Hospital, Boston, May 6, aged 44, of leukemia.

Whitaker, Leslie Stow ⊕ San Jose, Calif.; University of Louisville (Ky.) School of Medicine, 1926; affiliated with Santa Clara County Hospital and O'Connor Hospital; died May 10, aged 52, of coronary occlusion.

Williams, Dell E., Laguna Beach, Calif.; State University of Iowa College of Medicine, Iowa City, 1897; died April 29, aged 80, of cardiac decompensation.

Willis, David Arthur ⊕ Chicago; University of Illinois College of Medicine, Chicago, 1923; associate professor of surgery, Chicago Medical School; specialist certified by the American Board of Surgery; fellow of the American College of Surgeons; affiliated with Mount Sinai Hospital; died in the Garfield Park Community Hospital May 19, aged 52, of myocardial infarction.

Ziegler, Samuel Edgar, Piqua, Ohio; Starling-Ohio Medical College, Columbus, 1910; died March 8, aged 78.

GOVERNMENT SERVICES

ARMY

Promotions in the Surgeon General's Office.—Stars were pinned on two officers of the Medical Service in a ceremony July 7 in the Surgeon General's Office. Major Gen. Silas B. Hays, Deputy Surgeon General, was awarded his second star and Col. Rawley E. Chambers, newly appointed Chief of Professional Divisions in the Surgeon General's Office, became a brigadier general.

General Hays became Deputy Surgeon General last year after serving as surgeon of the Japan Logistical Command since early in the Korean conflict. In this assignment he was responsible for management of Army hospitals in Japan, evacuation of casualties from Korea, and furnishing of medical supplies and equipment to both Japan and Korea. During World War II General Hays served as chief of medical supply in the European Theater of Operations. He was awarded the Legion of Merit with Oak Leaf Cluster, the Croix de Guerre with Palm, and Order of Public Health from France for his work in that country.

In addition to being coordinator of seven professional divisions in the Surgeon General's Office, General Chambers will serve as chief of the psychiatry and neurology consultants division. He has served as chief of the neuropsychiatric service at Brooke Army Hospital, Fort Sam Houston, Texas, and director of the department of neuropsychiatry at the medical field service school there. Under his direction the child guidance clinic was created at the hospital. During World War II he was commanding officer of the 12th Evacuation Hospital, 805th Hospital Center, 77th Station Hospital, 7th General Hospital, and 7th Hospital Group in the European Theater. Among his awards are the Legion of Merit, World War II Victory Medal, and Commendation Ribbon.

NAVY

Physicians Needed for Marine Reserve Unit.—The First Engineer Battalion, Marine Corps Reserve, at Fort McHenry, Baltimore 30, offers an exceptional opportunity to physicians of e Navy Reserve. This unit is authorized to have two reserve ysicians. Membership in the unit will afford physicians an opportunity to earn retirement and promotion credit points and will not effect their status in regards to active duty. However, for physicians who do not desire to attend the two week summer training camp at Camp Lejeune, N. C., but who desire to affiliate with this unit, the status of appropriate duty is offered. In an appropriate duty status a physician receives the same benefits, but is not considered a member of the unit and will not attend summer camp. Navy Reserve physicians interested should telephone Lieut. Col. E. P. Moses Jr., Marine Corps, at PLaza 4132 or see him personally at Fort McHenry in Building 1.

Reserve Officers Receive Retirement Credit for Attending Convention.—The chief of naval personnel announces that Reserve Medical Department Officers will receive retirement point credits for attending the annual convention of the Association of Military Surgeons, meeting in Washington, D. C., Nov. 17-19, 1952. Reserve officers of the Medical, Dental, Medical Service, Nurse, and Hospital Corps, not on the inactive status list (Public Law 810, 80th Congress), will receive one retirement credit point for each of the three sessions attended, provided that the duration of the meeting is at least two hours. An officer designated by the chief of the Bureau of Medicine and Surgery will attend the convention and record the names of those attending, the sessions attended and the duration of each session.

Personal.—Rear Adm. Lamont Pugh, Surgeon General of the Navy, has been notified of his recent election to active fellowship in the American Surgical Association.

PUBLIC HEALTH SERVICE

Regular Corps Examination for Medical Officers.—On Oct. 7, 8, and 9, 1952, the U. S. Public Health Service will hold competitive examinations for physicians interested in appointment in the Regular Corps. Completed applications, accompanied by a birth certificate and transcripts, must be received in the Washington office no later than Aug. 26. Appointments are for career service and will be made in the grades of Assistant and Senior Assistant Surgeon, with salary and allowances totaling $6,017 and $6,918, respectively. Provisions are made for periodic promotion, liberal retirement benefits, sick and annual leave, and other benefits. Applicants must be citizens of the United States and graduates of a recognized school of medicine. Interns are eligible for admission to the examination. Additional information should be requested immediately from the Chief, Division of Commissioned Officers, Public Health Service, Federal Security Agency, Washington 25, D. C.

Survey of Equipment and Supplies for Hospitals.—Half of the nation's hospitals have completed and returned their questionnaires in the nation-wide survey of the needs of civilian hospitals for vital equipment and supplies, it was announced by the Surgeon General. The survey is being conducted by the American Hospital Association and the Public Health Service to provide information on the supply and equipment needs of hospitals as a basis for determining what production is required to meet these needs. With this information, the equipment and supply requirements of the nation's medical care facilities can be planned more accurately as military requirements rise. Wesley E. Gilbertson, chief of the Public Health Service's Division of Civilian Health Requirements, urges that hospitals that have not yet returned the questionnaire do so immediately.

It was emphasized that reliability of the survey will be helped if hospital administrators will (*a*) verify that the items reported are exactly the same as those requested on the questionnaire form, (*b*) make sure that each box in the heading on the form contains an entry, (*c*) convert information respecting quantities to the units of measure requested, and (*d*) carefully review the completed questionnaire before mailing, to eliminate typographical and other inadvertent errors.

Division of Occupational Health.—New staff appointments have been announced by the Division of Occupational Health, Public Health Service, coincident with the reorganization of the division that went into effect on July 1. The environmental investigations branch and the clinical investigations branch have been merged into a single investigations branch at Cincinnati, which will be headed by Dr. W. Clark Cooper. Dr. Cooper was formerly Deputy Chief of Medical Services in the Public Health Service Hospital, San Francisco. Dr. Dale C. Cameron, who had previously served as chief of the cooperative health services branch, is now in charge of the new program developments branch of the division. Mr. Henry Doyle, who was formerly in charge of the division's Salt Lake City field station, will direct the activities of the state aid branch. Both of these branches are located in the Washington office. Dr. Lewis J. Cralley has been assigned to direct the activities of the Salt Lake City field station. Prior to this new assignment, Dr. Cralley had served as chief of the environmental investigations branch in Cincinnati.

Field Work for Foreign Health Workers.—The Division of International Health of the Public Health Service recently assisted the Rockefeller Foundation and the World Health Organization in orienting into the field of public health two groups of foreign health workers who just graduated from various schools of public health in the United States. The students, who represented 18 different countries, were given field work in Mississippi, Georgia, and Tennessee. Following this they were placed in county health departments in five states for further training during the summer.

FOREIGN LETTERS

ARGENTINA

Congress of University Teachers.—From May 14 to 17 the first Congress of University Teachers was held in Buenos Aires. In Argentina there are only governmental universities, private ones not being allowed. In one of the initial speeches, President Perón was mentioned as the "archetype of the University professor." At the final meeting, the congress declared that the mission of Argentine universities is to promote and diffuse a national culture related to the Christian occidental civilization and in accordance with the national constitution. The congress requested that the rank of full professor be considered at the same economical rank of a judge and that the function of professor be incompatible with any other official position. The congress established 169 technical committees for the study of university problems. The congress asked that May 15 be declared the "day of the University teacher" and that the Confederation of University Teachers be called for an international university congress under the economic support of the government. President Perón delivered a speech at the final meeting of the congress.

Prizes Awarded.—The prize of the Severo Vaccaro Foundation (1951-1952) was awarded to Dr. Oscar Orias, director of the Mercedes and Martin Ferreyra Institute for Medical Research, a private scientific nonprofit laboratory in Cordoba, supported by public gifts and in great part by resources granted by many Rotary Clubs of Argentina. Dr. Orias was a pupil of Professors C. Wiggers (Western Reserve), W. B. Cannon (Harvard), and B. A. Houssay (Buenos Aires), and was visiting professor of physiology in Long Island College of Medicine from 1948 to 1949. His principal researches have been on heart dynamics in coronary ligation, experimental and clinical branch blocks, gallop rhythm, and hypertension. He wrote, with E. Braun-Menendez, a book on heart sounds, which has been translated into English. He has developed modern scientific methods for all the cardiologists of Argentina. His researches on hypophysis are very important, including studies of action on heart and blood pressure and regulation of sexual function in batrachians. With his pupil Ines de Allende he recently wrote a book "Cytology of Human Vagina," translated by Dr. George Corner. Dr. Orias has been a hard-worker, a brilliant and stimulating teacher, and a man of the highest integrity and energy, who has devoted full time to research and teaching.

The annual prize of the Circulo Medico de Rosario was awarded to Drs. J. J. Staffieri and L. J. Cardonnet for clinical work on NPH 50 (modified protamine) insulin. The Argentine Medical Association awarded the Guillermo Rawson prize to Dr. J. C. Loza Colomer for his paper on "Organization of General Hospitals" and the Pedro O. Bolo prize to Drs. A. Lanari, M. Molins, and O. C. Croxatto for their experimental work on pulmonary graft. The prizes for the best medical thesis in 1951 were awarded to Drs. R. R. Rodriguez, M. A. Pico, and Gil Marino by the School of Medicine of the University of Buenos Aires.

Finlay Commemoration.—The Ministry of Public Health has organized many ceremonies in commemoration of the historical discovery by Carlos Finlay from Havana, Cuba, of the mosquito as a transmitter of yellow fever. In a ceremony attended by Pres. Juan Perón, held on May 20, a bust of Finlay was unveiled in the Policlinico Central. Moreover, one street in Buenos Aires has been named Carlos Finlay.

ISRAEL

Superinfection of Leishmania Tropica in Leishmaniasis.—Successful experimental superinfection of Leishmania tropica in patients with relapsing cutaneous leishmaniasis has been performed by Dostrovsky, Sagher, and Zuckermann of the dermatological department of the Hadassah University Hospital in Jerusalem. L. tropica in a susceptible human subject ordinarily produces a lesion that heals totally and spontaneously, leaving no residual parasites. The cured host generally remains immune for life and is refractory to natural reinfection. A small percentage of patients, however, are unable to eradicate the parasite, and their initial lesions continue to grow for years owing to successive relapses, with active peripheral foci surrounding a central scar. This lesion is known as leishmaniasis recidiva.

The investigators attempted to determine whether such patients with relapsing cutaneous leishmaniasis were susceptible to experimental superinfection with cultures of a strain of L. tropica capable of inducing typical primary nodular cutaneous lesions in subjects not previously exposed to leishmania organisms. Six patients with leishmaniasis recidiva, therefore, received intradermal inoculations consisting of 1 to 10 million washed culture flagellates of L. tropica over the left and right deltoid regions, respectively. Aspirated juice from the lesions developing at the inoculation sites yielded positive cultures in five of the six patients 1 to 15 weeks after inoculation, proving the subjects susceptible to superinfection.

Superinfection lesions obtained in these patients closely resembled relapse lesions and not initial (nodosa) lesions, as shown by the following lines of evidence. 1. Superinfection and relapse lesions consisted of yellowish-brown infiltrates with peripheral "apple jelly" nodules of granulation tissue revealed by diascopic pressure, as contrasted with typical nodosa lesions, which are reddish-blue and have no apple jelly nodules. 2. Superinfection lesions, like relapse lesions, were composed of tuberculoid tissue from their inception until cicatrization, as contrasted with the histocytic structure of the typical nodosa lesion. 3. As in relapse lesions, very few parasites were found at the superinfection sites. Microscopic examination was regularly negative, and not all tubes seeded with tissue juice yielded positive cultures. In contrast, parasites are generally numerous enough in the primary nodosa type lesion to be demonstrated microscopically, and all tubes seeded from such lesions are regularly positive. This phenomenon consisting in the development of a lesion resembling the relapse type rather than the primary type at the site of superinfection in patients suffering from relapsing cutaneous leishmaniasis has been designed as an "isophasic reaction."

Diagnosis of Leprosy.—The long incubation period of leprosy is the greatest obstacle in the exact diagnosis of this disease. Through the experimental studies of Sagher, Kocsard, and Liban, it has now become possible to answer the question of whether there is an acute infection. The first observation brought the result that histological examinations following tuberculin, leishmanin, milk, and peptone injected in the skin of leprosy patients showed the development of a granulomatous reaction indistinguishable from lepromatous leprosy. Furthermore, inoculations of BCG vaccine in leprous patients produced clinically typical lesions. The histological examinations from these lesions, however, revealed a granulomatous tissue reaction indistinguishable from true lepromas. It seems, therefore, that lepromatous leprosy produces only its own histopathological response notwithstanding the cause of the lesion produced. These facts may be of importance for criteria of cure from this disease, since the response was still present in patients after disappearance of

---

The items in these letters are contributed by regular correspondents in the various foreign countries.

clinical signs and bacilli. Further, early cases may be detected even in the incubation period by performance of those tests and histological findings of lepromatous granulation tissue. So far, no other known disease reacts in this way.

Antimalaria Work.—According to Dr. J. Saliternik, the annihilation of Anopheles mosquitoes is found to be the most effective method of controlling malaria in this country. The most important malaria vectors today are the Anopheles sacharovi and Anopheles sergentii. Till 1945 Anopheles sacharovi, a domestic mosquito, was considered the main malaria vector. Since then it has decreased in number as well as in importance, as a result of the use of D.D.T. sprayed systematically in all malarious districts. The most dangerous mosquito in the country today is the Anopheles sergentii. Being a half domestic mosquito it cannot be sufficiently affected by residual sprayings.

A survey of all the water courses, potential Anopheles mosquito breeding places, in this country showed: 17,878 wells, 558 natural water courses of 1,236 km., 7,500 dunams of swamps (not including the Hule), and 23,467 dunams of fish ponds. In 1950, 28,000 working days were invested for chemical and technical treatment.

The fight against the adult Anopheles mosquito is carried on by residual D.D.T. spraying (5% D.D.T. solution in gasoline). In 1950, 412 tons of D.D.T. solution were used in spraying 344 settlements in malarious districts, comprising 105,714 rooms and a population of 152,690. Antimalaria work is carried on in accordance with climatic changes, population movements, the biology of the various Anopheles species, and periodicity of the malaria seasons.

As a result of the systematic antimalaria work, there has been not only a marked reduction in the number of new malaria cases (in 1950 only 842 cases were registered), but the whole epidemiological picture was completely changed. Formerly, there were two peaks in the malaria curve, one in spring in the coastal regions in particular, caused by Anopheles sacharovi, and the second in autumn in the interior of the country, where the main vectors are Anopheles sergentii and Anopheles superpictus. Now with the reduction of Anopheles sacharovi the first peak has nearly completely disappeared, and in the second there has been a considerable decrease, too.

New Department of Anatomy.—The Hebrew University-Hadassah Medical School formally inaugurated its new department of anatomy in the presence of a large number of teachers and students. The dean of the school, Professor Dostrovsky, explained that exceptional prominence was being given to the in- auguration of the courses in anatomy not only because it is a basic subject in the study of medicine but also because its in- clusion in the curriculum is a vital matter for the school itself. The many difficulties inherent in giving anatomy courses in Israel have been surmounted owing to the help extended by the ministries of health and justice and by the Anatomy Law. The opening lecture was given by Dr. M. Izkovitz, lecturer in anatomy, who described the history and development of that science through the ages. Just three years after the opening of the Hebrew University-Hadassah Medical Faculty in Jerusalem, the first class of 62 students received their Doctor of Medicine degrees in May, 1952.

New Tuberculosis Center Near Jerusalem.—The formal opening of the Eytanim tuberculosis center at Deir Amr in the Jerusalem Corridor took place in May, 1952. The 225 bed hospital has a children's section, which already cares for 100 patients. It is named in the memory of the late King Christian X of Denmark. Most of the funds necessary to equip the section were contributed by the Danish government and Danish citizens. The Danish minister to Israel, Mr. Hans P. Hoffmeyer, and representatives of the Danish Jewry attended the opening ceremony.

During the inspection of the hospital, Dr. Y. Chasis, head of the health ministry's tuberculosis department, disclosed that about 4,000 persons suffered from tuberculosis in Israel, al- though, as in every country, no exact figure is available since not all ill persons report to the authorities. Israel has at present 108 beds per 100,000 population, but it plans to raise the number of beds to 130. This figure can be considered very favorable when compared with most other countries in the world.

The Eytanim center will be expanded to hold 300 beds. Using an idea developed successfully in Switzerland, a number of prefabricated huts have been set up for former adult patients who wish to work for the hospital after their discharge as patients. By this method it is hoped that the shortage in personnel will be overcome. At present, the personnel numbers 0.5 per bed, while the international standard is 0.7.

NORWAY

Laboratory Control of BCG Vaccine.—Last May the University of Bergen conferred an M.D. degree on Dr. E. F. Krohn for his work there on the laboratory control of BCG vaccine. His work is published as "Supplement 30" to *Acta tuberculosea Scandinavica.* The cost of his investigations, which were prompted by the director of the laboratory, Dr. J. Böe, was borne by the Norwegian National Association Against Tuberculosis. The effects of the vaccines on human beings examined by Krohn were controlled by the tuberculosis department of the Oslo Public Health Service and by the state photofluorographic service. The first BCG culture was brought to Bergen by Birkhaug in 1937 from the Pasteur Institute in Paris, and both the strains employed by Dr. Krohn were derived from a culture obtained in 1945 from the same institute. The Bergen laboratory issues two types of vaccine, one concentrated and containing 20 mg. BCG moist weight per ml., and one diluted to contain only 1 mg. BCG per ml. Krohn's investigations were concentrated on the latter, which is intended for intracutaneous injection.

Since the success of the BCG campaign throughout the world must ultimately hinge on the reliability of the laboratory control of the vaccine, Krohn's work may be said to be of vital importance to millions. Yet it is so highly technical that most of his book will be understood by only a few of his fellow workers. But even for persons to whom mathematical formulas and the finesse of laboratory technique mean little, there is much in this book to stimulate and interest them. Dr. Krohn has come to the conclusion that no definite correlation can be established between the number of viable bacillary particles and the effects of the vaccine on human beings. "Such effects would seem, accordingly, to be determined in the main by qualitative properties, the demonstration of which is not possible by ordinary laboratory methods, but will require biological tests." A series of investigations of the immunizing effects of Norwegian BCG vaccine on mice is being planned as part of the present study. They are still at a preparatory stage and will therefore be published separately. In the present work a summary after each chapter and a comprehensive summary at the end of the book are helpful in giving a bird's-eye view of Dr. Krohn's main conclusions. His bibliography contains 172 references.

Fewer Days in Hospital.—There is a general impression, not always substantiated by reliable statistical evidence, that in countries with a high cultural level patients spend fewer days in the hospital than they did a few years ago. Herr E. W. Østberg, who is attached to a statistical bureau run by the municipal authorities of Oslo, has recently provided such evidence on the basis of 11,548 patients treated in certain hospitals in Oslo during the years 1928, 1937, and 1947. During this 20 year period, the average duration of treatment in a hospital was reduced from 28.9 days in 1928 to 20.6 in 1937 to 19.9 in 1947. It will thus be seen that this reduction was much greater in the first than in the second decade under review. Since it can be assumed that the duration of treatment in the hospital rises with the average age of the patients and since the average age of the patients has risen in this 20 year period, this reduction in the duration of treatment in hospitals is, indeed, a remarkable achievement. The relative upward shift of old persons in a given community was estimated in 1948 to be such that in 1920 only

3.3% of the total population of Oslo was 70 years old or older, whereas the corresponding figure in 1948 was 5.8%. In 1928, approximately one-third of the male patients studied by Østberg were under the age of 30, whereas in 1937 they represented only 20.1% of all the male patients, and in 1947 only 13.9%. A classification of the patients according to the diseases for which they were treated in the three years under review showed that there was a relative rise in the number of cases of heart disease. This rise may well reflect the greater average age of the patients. Between 1937 and 1947 there was a marked rise in the relative frequency of all forms of pneumonia.

Education in Mental Hygiene.—The Norwegian Mental Hygiene Association, whose chairman is Dr. Gordon Johnsen, last May launched a mental hygiene education campaign with two main interests. One of them is the child of preschool age and its home. The other is the employer and the employee and the parts they play in industry. Speaking on the first subject, Dr. Johnsen pointed out that the only mental hygiene polyclinic for children in Oslo has so many requests for service and so long a waiting list that up to three months have to pass before some cases can be dealt with. Yet this polyclinic is threatened by closure for want of the necessary funds. Dr. Johnsen said that the Mental Hygiene Association is planning the creation of several more polyclinics along similar lines. With the help of such powerful voluntary organizations as the National Association Against Tuberculosis and for Health, as well as the Red Cross, he hopes to organize mental hygiene teams composed of psychiatrists, psychologists, and social workers. He assured his audience that psychic disturbances were just as common in children of the preschool age as among adults.

Speaking on the same occasion, Dr. Karen Margrethe Simonsen, who was recently imported from Denmark to take charge of the new psychiatric department for children at the Rikshospital in Oslo, compared the mentalities of Norwegian and Danish children. She has come to the conclusion that in Norway the most common cause of faulty mental development in the child is the strait-laced and inhibited outlook of the parents. Inhibited by moral scruples in their emotional lives, they are apt to impose an excess of moral responsibility on their children who develop compulsion neuroses in consequence. She has found cases of this type to be much commoner in Norway than in Denmark whose population has a more open and less inhibited emotional outlook. At the Rikshospital about half of all her patients are children under school age. She is convinced that treatment given early enough, during the first years of life, has an influence on the subsequent development of the personalities of such children.

Opening of Audiological Institute in Oslo.—On May 21 the new Audiological Institute within the framework of the Rikshospital in Oslo was opened formally by the university's rector, Herr F. Castberg. It is the only institute of its kind in Norway, and it owes its creation to the generosity of a whale oil magnate, Herr Anders Jahre, whose donation of 150,000 k. has been supplemented by the sum of 75,000 k. for working expenses during the first five years. The institute is linked up with the ear, nose, and throat department of the Rikshospital, in the new surgical block. Professor Opheim, who is in charge of this department, pointed out at the opening ceremony that there are some 60,000 persons in Norway who are completely deaf, and that about 10% of the whole population suffer from defective hearing. Yet in spite of the enormous social problems raised by this form of invalidism, it was only in recent years that attempts had been made to solve them on a medical and scientific basis. The nucleus of the institute consists of a laboratory and three soundproof rooms.

The publicity given to the problems of noise and deafness in both the lay press and the medical press in recent years reflects the active interest now being taken in the prevention of defective hearing. Dr. S. Quist-Hanssen has recently published studies on this subject and has shown how much the success of ear plugs depends on the care with which they are fitted. Audiometric control of such fitting requires only a few minutes and, when supplemented by instruction in the use of such plugs, should do much to assure their success. Glass fiber wool has gained favor since an account of its use was given in May, 1951, in Helsingfors at the Scandinavian Congress for Industrial Medicine. Made from melted glass, the diameter of its fibers is only about one-tenth of that of cotton wool fibers. Dr. Quist-Hanssen has found no great difference in the effects of glass fiber wool according to whether it was lightly or tightly compressed, but other observers disagree with him on this point. A drawback to this preparation is, in his opinion, its tendency to deposit some dust in the ear passages. But they do not become irritated even when the glass fiber wool is used daily for several months. Its cheapness is also a point in its favor. It is with this problem and many others that the institute in Oslo will now be working.

TURKEY

Schistosoma Haematobium Investigation.—The Ministry of Health and Social Assistance appointed Prof. Zühdi Berke and microbiologist Dr. Tahsin Berkin of the Refik Saydam Central Institute of Hygiene, Ankara, to report on Schistosoma haematobium in the southern provinces that border Syria and Iraq. In 1939 an increase in schistosomiasis in Syria was noticed. French regiments from the Senegal, who had been stationed there from 1936 to 1941, and 60 to 70% of the Syrian population along the Syrian-Turkish border became infected. As a result of an investigation made by specialists from the Syrian Ministry of Health and in cooperation with experts from the American Medical School in Beirut, tentative control was instituted in 1948. Investigation by Prof. Zühdi Berke and Dr. Tahsin Berkin revealed the presence of two Schistosoma haematobium centers near the Turkish border. One center was in the Kuburelbeyd village, population about 1,000, 15 miles south of the Turkish border, and also in the Tel Hasnak village, 3 miles from the Turkish border. The second center was in the Tel Abyad village, 125 miles east of Halep (Aleppo) and south of the Turkish district of Akça Kale, population about 76,000, and in almost 1,000 other villages. Three streams traverse this territory. Along the Djerrahi River, from 8 to 34% of the population were affected, along the Sublah River 15 to 24%, and along the Katraniye River 10 to 40%. All patients were given treatment. Under the direction of an expert from Egypt, a schistosome prevention and control unit was equipped with a mobile hospital and laboratory to take up its activities in this territory. Investigations along the Turkish-Iraqian border confirmed that urinary schistosomiasis is endemic in Iraq. During the hot summer season, June to October, the population bathes in the streams and rivers spreading infection. Ponds and swamps, resulting from inundations, water plants along slowly moving rivers, and rice fields favor the propagation of infected snails.

Hospitals, dispensaries, and health propaganda in Iraq have resulted in a reduction of schistosomiasis and prevented more serious outbreaks. The economic aspects of the damage caused by snails has been investigated by Mr. John Watson, an expert who recommended more radical measures, and the World Health Organization has decided on an effective program for the control of the schistosomiasis scourge.

According to the report the Ministry of Health received from Prof. Berke and Dr. Berkin, there are no persons affected with schistosomiasis in the Turkish border districts of Akça Kale, Idil, and Nusaybin, or in the surrounding areas. Random urinalyses on hundreds of adults and children had negative results. Investigation at the Central Institute of Hygiene, Ankara, of mollusks from the streams and rivers traversing the three territories revealed that they were not Schistosoma haematobium hosts, Bulinus contortus, nor, though they were found in the Suruc Stream, were they infected. This corroborated the findings of Dr. Fehmi Derbent, who, in cooperation with local municipal health officers, had previously made an investigation for the Ministry of Health.

CORRESPONDENCE

TOUR TO WORLD MEDICAL ASSOCIATION MEETING IN ATHENS

To the Editor:—To facilitate travel to the Sixth General Assembly of The World Medical Association, in October, 1952, World Travel Plan has arranged a guided tour by airplane charted through an internationally known scheduled airline, namely, Sabena Airlines.

The trip will include tours of Rome, Geneva, and Paris, as well as a stay in Athens during the period of the General Assembly. The total cost is $789.00 per person, which is about $250.00 per person less than the cost of a round trip by air alone. The $789.00, however, does not include expenses in Athens, which will be in addition to the above amount. The proposition would seem to be advantageous to those who are contemplating the trip and who would like to make the tours of the other cities at the same time.

The itinerary for this tour is as follows.

DATE	PLACE	ITINERARY
Wed., Oct. 8	At New York	Accommodation provided at Hotel Roosevelt, Madison Ave. at 45th St., New York City.
Thu., Oct. 9	Leave New York	After breakfast at hotel, final check of documents and discussion. Transfer by private motor direct to Idlewild International Airport. Check in at airport and leave early afternoon by first-class D.C.-6 plane of Sabena Belgian Airlines. All meals with beverages included.
		GREECE
Fri., Oct. 10	Arrive Athens	Arrive afternoon. Transfer by private motor to hotel.
Sat., Oct. 11 to Fri., Oct. 17	At Athens	Attending the Sixth General Assembly of the World Medical Association.
Sat., Oct. 18	Leave Athens	After breakfast, transfer by motor direct to airport. Leave Athens by plane.
		ITALY
	Arrive Rome	Arrive about noon. Transfer by motor to hotel. Afternoon: A general drive and survey of the city, returning to the hotel for dinner.
[illegible], Oct. 19	At Rome	This morning is available in Rome for individual action. Afternoon: Special drive to Tivoli, proceeding along the Via Tiburtina to Acqua Albule (sulfur baths), Ponte Lucano, Tomb of Plautius Lucanus to Hadrian's Villa. Continue to the Villa d'Este (visit the grounds with many fountains, artificial grottos, and pavilions); drive to the Temples of Vesta, Sybil, and Hercules and to the waterfalls of the Anio. Return to Rome for dinner.
Mon., Oct. 20	At Rome	This morning is free in Rome. Afternoon: A general drive and survey of the city.
Tue., Oct. 21	At Rome	This day available for individual action.
Wed., Oct. 22	Leave Rome	After breakfast, transfer by motor direct to airport. Leave Rome by plane.
		SWITZERLAND
	Arrive Geneva	Arrive early afternoon. Transfer by motor to hotel. Balance of day free.
Thu., Oct. 23	At Geneva	Survey of the city, then by lake steamer on Lake Geneva (Swiss and French side) including Montreux (Chillon Castle) and Lausanne.
Fri., Oct. 24	Leave Geneva	After breakfast, transfer by motor direct to airport. Leave Geneva by plane.
		FRANCE
	Arrive Paris	Arrive about noon. Transfer by motor to hotel. Afternoon by motor for a special tour of this fabulous city.
Sat., Oct. 25	At Paris	After breakfast, by motor for additional city touring. Continue to Versailles for luncheon and visit the famous palace. Back to the hotel for dinner.
Sun., Oct. 26	At Paris	This day available for individual action.
Mon., Oct. 27	At Paris	Full day free for shopping (expert guide provided). Fashion show, additional local visits, or special interest program. Special luncheon provided at famous Parisian restaurant.
Tue., Oct. 28 and Wed., Oct. 29	At Paris	Days free. Tickets provided for Folies Bergère or similar show, the opera, etc.
Thu., Oct. 30	Leave Paris	Transfer by motor direct to airport for overnight flight home. All meals provided.
		UNITED STATES
Fri., Oct. 31	Arrive New York	Arrive International Airport. Motor transportation provided into New York City.

Louis H. Bauer, M.D.
Secretary-Treasurer
World Medical Association
2 E. 103rd St., New York 29.

"TELEVISION NECK"

To the Editor:—For many years, I have had a special interest in musculoskeletal disorders. As part of every physical examination, I have measured joint mobilities according to the methods described in my monograph "The Common Form of Joint Dysfunction" (Brattleboro, Vt., E. L. Hildreth & Co., 1949).

Recently I have observed a clinical syndrome in persons who, in watching television programs, maintain strained postures of the head and neck, often for prolonged periods. The manifestations of this syndrome, which for want of a better name can be called "television neck," include measurable increased limitation in ranges of neck movement and pain or discomfort in the posterior nuchal region (with or without radiation of pain or discomfort into the shoulders, upper back, or occiput). In many of these patients, the faulty sitting and erect posture that is maintained when they are not viewing television is a result of the tendency to flex the neck on the trunk and extend the head on the neck to maintain the face roughly parallel to the frontal plane of the body and to the television screen. There is also some concomitant exaggeration of the upper dorsal curvature, suggesting a mild or moderate upper dorsal kyphosis. When television neck occurs in both husband and wife and each has a favorite chair and position for viewing television, the limitation in movement and the discomfort occur mainly on one side in the husband and on the other side in the wife.

When several persons view the same screen, there is also sustained lateral bending of the neck. The relatively fixed position of the head, neck, and upper trunk is associated with symptom-producing neck muscle hypertonia and increased static postural traumatization of the articular surfaces of the cervical and upper thoracic vertebrae.

The remedy—aside from not viewing television—is to raise the television set so that the screen can be comfortably viewed by each person without assumption of this awkward sustained posture. Sometimes a chair with a lower or higher seat permits less strained posture.

Since television viewing in the home and elsewhere is likely to increase, physicians should be alert to recognize the syndrome of television neck and to prescribe proper treatment. Television equipment and furniture designers should be encouraged to develop home equipment that will make it possible for the viewer to enjoy television programs without maintaining strained posture for prolonged periods.

William Kaufman, Ph.D., M.D.

Bridgeport 4, Conn.

A SIMPLE EVALUATION OF FOODS

To the Editor:—A question frequently asked, mostly by laymen, pertains to the relative value of different foods: "Are carrots a better food than potatoes?" "Do beets have much food value?" "How do spinach and kale compare in food value?" Obviously, if one were completely or largely on a potato diet, carrots in the diet would have a far greater value than an equal amount of potatoes. Yet conceivably there are diets that could not be improved by the addition of carrots.

It is realized that such questions have something in common with the question "Which is the more important, the hen or the egg?" The completely evasive, though inescapable, answer to the hen and egg question is that without one there cannot be the other. It is possible, however, to give a better answer in a comparative evaluation of different foods. The first requisite in such comparisons is to have representative analytical figures as to the content of the critical dietary essentials in any one food. Counting the essential amino acids, there are about 50 dietary essentials. Not all are critical in the sense that there is any danger of our not receiving an adequate supply, regardless of what our diet may be.

The Nutrition Board of the National Research Council, in setting up the recommended daily dietary allowances, gave recognition to what are commonly regarded as the critical dietary essentials. The recommended amounts naturally vary with the person, being affected primarily by age and activity and, to a lesser extent, by size and sex. For the purpose of the comparative evaluation of foods in the accompanying table the values for a 154 lb. (70 kg.) sedentary man and a moderately active 123 lb. (56 kg.) woman are used, since they are alike for most of the nutrients, and, in cases in which they differ, the median value has been used. These values are as follows: calories 2,400; protein 65 gm. (median, between 70 for the man and 60 for the woman); vitamin A 5,000 I. U.; thiamine 1.2 mg.; riboflavin 1.65 mg. (median between 1.8 for the man and 1.5 for the woman); niacin 12 mg.; and ascorbic acid 72.5 mg. (median between 75 for the man and 70 for the woman). It may be added that the use of these median values instead of the exact figure

Ratio of Daily Requirement of Nutrients to Daily Requirement of Calories in Foods *

	Protein (65 Gm.)	Ca (1,000 Mg.)	Fe (12 Mg.)	Vitamin A 5,000 I. U.)	Vitamin B_1 (1.2 Mg.)	Vitamin B_2 (1.65 Mg.)	Niacin (12 Mg.)	Vitamin C (72.5 Mg.)	Average

* Daily requirement is given in parentheses under each nutrient.

for a man or for a woman has no significant effect on the figures in the accompanying table.

The literal meaning of the figures may be illustrated with canned white asparagus, since it stands at the head of the list. It is not intended to suggest that any sedentary man or moderately active woman is ever going to eat enough white canned asparagus in a single day to provide the entire recommended daily requirement of 2,400 calories. But, if one supposes that this amount were consumed in one day, and it alone, 3.1 times the recommended protein would be supplied, 1.8 times the recommended calcium, 8.8 times the iron, 1.2 times the vitamin A, 4.9 times the thiamine, 4.6 times the riboflavin, 6.9 times the niacin, and 24 times the ascorbic acid (vitamin C).

In a similar manner, the meaning of the average figures at the bottom of the list of canned foods becomes clear. If the daily recommended calories were obtained by taking an equal number of calories from each of the 35 canned foods listed (a vegetarian diet), those canned foods would supply 1.3 times the recommended protein, 1.5 times the calcium, 7.3 times the iron, 20 times the vitamin A, 1.8 times the thiamine, 2.1 times the riboflavin, 2.8 times the niacin, and 17 times the ascorbic acid.

There is good reason for evaluating foods on the basis of the amount of the protein and noncalory nutrients supplied in proportion to the calories. Of all the factors for which the Nutrition Board has made recommendations, only calories are directly related to the amount of food consumed. If we eat less food than will supply our normal requirement of calories, we will lose weight; if we eat more, we will be burdened with overweight, and obesity is a major problem in nutrition. But no suggestion has ever been made of our getting harmful amounts of any of the other nutrients from our foods; the concern has been entirely with our getting the recommended amounts, and it has been intimated that greater amounts are all to the good.

The average figures in the last column of the table serve as rough comparative value of individual foods in their ability to supply critical nutrients; for example, 0.5 for pears as against 10.7 for green asparagus leaves little doubt about the comparative value of the two. But the figure 27.7 for carrots is largely due to the very high value (208.5) for vitamin A. All the other values for carrots, with the exception of that for calcium, being *materially lower than for green asparagus.*

The values for the canned foods have been calculated from the data in "Canned Foods in Human Nutrition" (Washington, . C., National Canners Association, 1950). This represents the st comprehensive analytical survey of any class of food. undreds of samples from the entire country were collected, and the analyses were made in the nutrition departments of nine of our great universities. The values for the noncanned staple foods are from data in the U. S. Department of Agriculture Handbook no. 8, June, 1950.

Since the data in the table are based on chemical and microbiological technique they reveal nothing regarding availability. When there are data on availability, the figures in the table will assume far greater accuracy. It should also be remarked that nitrogen content is not a true measure of protein value; also, the high calcium content of spinach is known to be of little value nutritionally. In spite of these shortcomings some definite conclusions are evident. The vegetables as a group are outstanding in providing an abundance of all the critical nutrients in proportion to their calory value. They outrank the so-called staple foods and the fruits. As a class, fruits and vegetables supply vitamins A and C in great abundance. Since the ratio of vitamins A and C to calories is 20 and 17 for the canned vegetables and fruits, respectively, our vitamin A requirement would be met if they supplied but 5% of our calories and our vitamin C requirement would be met if they supplied 6% of our calories. While the data pertain more specifically to canned vegetables and fruits, they no doubt apply to other foods, irrespective of form.

CONTRIBUTION BY INDUSTRY TO MEDICAL EDUCATION

To the Editor:—The efforts to persuade industry of its share in the responsibility for the financial support of medical schools is well known to us all and is an endeavor of the greatest importance. This problem is so immediate and so vital that it tends to overshadow a second problem, of which I am writing you today.

The rapidly rising costs to the student in medical school have placed an extraordinarily heavy financial burden on each candidate, while at the same time the demands of the current-day curriculum make the time available for outside earnings insignificant for the most part. During this same time, as you well know, the income from scholarships and endowments has diminished. Were it not for the fact that the future of the medical school itself is at stake, this current dilemma of its students would assume much greater prominence.

Recently one of the pharmaceutical companies has recognized this as a special problem and has seen fit to give to every approved medical school in the country $1,000 to be disbursed to students in need. This action by a pharmaceutical company seems to me to deserve recognition by the members of the American Medical Association, who are so interested in seeing problems solved through the efforts of private enterprise.

If the board of trustees of such companies as the Charles Pfizer Company, which made the above-mentioned donation, can be encouraged by appropriate recognition to increase and to generalize their donations to medical education they could provide a large part of the total needs of the medical schools. Although $70,000 is not large in terms of the total need, it does seem to indicate a recognition by a pharmaceutical company of a direct responsibility for the needs of medical education. It would be regrettable if this sense of responsibility were not encouraged.

CHICAGO MEDICAL BOOK COMPANY

To the Editor:—We wish to inform your readers that the Chicago Medical Book Company has had nothing to do with nor did we know anything about the printing, publication, or distribution of a pamphlet, "The Hospital Superintendent: What Makes Him Tick?" This is reported to be a study in human behavior, but it is unsigned, and there appears to be no way of identifying the author or sponsor. Unfortunately, at the end of the document appears this statement: "Additional copies of this book may be obtained from the Chicago Medical Book Co., Jackson and Honore Streets, Chicago, Illinois."

The Chicago Medical Book Company has never been contacted by any person or persons requesting the use of our name with regard to this book or a book of this nature, nor have we ever given our permission to any person or persons allowing them the use of our name for the sale, distribution, or procurement of this book. We are completely ignorant as to what person or persons would use our company's name on the last page of this book as a source of supply. Until the post office called us about postage due on 120 of the booklets, we knew nothing whatever about it. We have had many requests, emanating from various sections of the United States, requesting additional copies of this booklet.

We are most desirous of correcting this unfortunate incident and take this opportunity to inform your readers of the above facts. In the event that they have any information regarding this publication, we would be more than happy to be advised of the same.

MEDICAL LIBRARY OF A NON-UNIVERSITY GENERAL HOSPITAL

A Five-Year Progress Report on the Medical Library of the New Britain General Hospital

Paul D. Rosahn, M.D.
and
Sadie M. Karpman, New Britain, Conn.

The New Britain General Hospital is a general, nonprofit association hospital of 267 beds. It is the only hospital of its type in an industrial community that, with its suburbs, has a population of approximately 100,000. The active, courtesy, and general practice staffs consist of 84 physicians, of whom 35 have been certified by various specialty boards. An approved residency training program is conducted in surgery, gynecology, obstetrics, internal medicine, and pathology.

The Hospital Medical Library was reorganized in 1946, pending completion of its present quarters, which it occupied in June, 1947. The area presently assigned to the library consists of a main reading room with tables and chairs accommodating about 15 persons, an adjacent stack room, and a nurses' reading room, located in the dormitory of the School of Nursing. An earlier report[1] outlined the developmental background of the library and discussed the guiding principles under which it operates. During the past five years there has been ample opportunity to test the original thinking on the organization and administration of the library against actual experience. Many ideas have been altered and revised in the light of this experience, and new thoughts have been incorporated in the program. The present five-year progress report has been prepared in the hope that it may be helpful to other non-university hospital groups interested in establishing a medical library in their institutions.

THE LIBRARY COMMITTEE

From its inception, the professional supervision and control of the library has been vested in a committee of the medical and nursing staffs. This committee, appointed by the board of directors of the hospital, is directly responsible to the board. The library is a recognized department of the hospital, and the librarian, as a hospital department head, is administratively responsible to the managing director.

The library committee[2] is composed of five members, two of whom, the director of nursing service and the school of nursing and the pathologist, are full-time hospital employees. The other three members, selected from the active medical staff, are each appointed for staggered three-year terms. Regular meetings of the committee are held each month, the librarian acting as secretary. Minutes of the meeting are recorded, and copies are distributed to each member of the committee, to the managing director, and to the librarian. Special meetings to consider urgent problems may be called by the chairman of the committee. The appointment to the library committee of the director of nursing service and the school of nursing is in accord with the originally stated policy of combining the library of the School of Nursing with the medical library.

Each member of the committee has recognized the great responsibilities of his office, and rarely does a member fail to attend the scheduled meetings. These are largely concerned with reviewing suggestions presented in writing by members of the medical staff for the purchase of textbooks or journals and acting on these recommendations. Such decisions are usually based on the general usefulness of the textbook or journal to a staff of varied interests and specialty training and always with the keen awareness of a relatively limited budget. In actual practice, the total annual budget is determined by the managing director, but the distribution and allocation of funds within the budget rest largely on the recommendations of the library committee. Other matters under discussion are such items as coverage during the librarian's vacations and other absences, the purchase of additional book shelves and large equipment, methods for increasing the usefulness of our facilities to the professional staff, and continuing thinking on ways and means of enhancing the attractiveness of the library quarters. The library committee has disapproved the use of the library reading room for small meetings or classes. The library committee believes that these activities would deprive members of our professional staff of the use of the library facilities during the meetings and would thus defeat a primary objective of the library, namely, round-the-clock accessibility.

FINANCES

Since a hospital library is a nonincome producing unit of the institution, its financial support must be derived from endowments, from contributions, or from general funds. Originally it was hoped that our library would be at least partially sponsored by specific bequests, but this hope has not been realized and we have had to depend on the other two sources to secure our operating funds. The members of the medical staff, at the inception of the program, in 1946, unanimously approved a self-imposed library tax of $15 each per *annum*, and without dereliction this amount has been subscribed each year. The treasurer of the staff transfers these library dues to the hospital, which ear-marks them for library use. In addition, small library fees paid by student nurses are allocated to the library fund. These monies comprise less than one-fourth of our total annual expenditures, the remainder being provided by the board of directors from other sources. The action of our directors in so generously supporting a hospital activity that is all too frequently by-passed or ignored is a tribute to their deep interest in developing and maintaining high medical standards.

New Britain General Hospital Library
Original Budget, Actual Expenditures from 1946 Through 1951 and Anticipated Budget for 1952

	Journals	Binding	Textbooks	Miscellaneous and Salaries	Total
Original Budget	$1,000.00	$1,000.00	$500.00	$2,500.00	$5,000.00
Actual Expenditures					
Nov., 1946-Sept., 1947	999.43	397.32	601.90	2,438.54	4,437.19
Oct., 1947-Sept., 1948	969.99	487.61	537.50	3,033.38	5,028.48
Oct., 1948-Sept., 1949	1,081.81	264.86	227.15	3,048.76	4,622.58
Oct., 1949-Sept., 1950	1,210.79	756.55	168.47	3,361.99	5,497.80
Oct., 1950-Sept., 1951	1,181.42	543.42	375.26	3,547.63	5,647.73
Anticipated Budget, 1951-1952	$1,200.00	$ 550.00	$500.00	$3,897.00	$6,147.00

LIBRARY BUDGET

Actual experience has produced two significant changes in our original tentative annual budget, as shown in the table. We overestimated the cost of binding our journals—all our journals are permanently bound promptly on the completion of a volume—and we did not foresee the general inflationary trends that would require upward adjustment of the salary paid to our full-time librarian. In spite of these developments, the total expenditure for the five-year period exceeded the anticipated operating expenses of $25,000 by only $233.78. Approximately 25% of the total was derived from staff dues and nurses' library fees. During the current fiscal year, the hospital will spend out of general funds about $5,000 for library purposes.

LIBRARY CONTENT AND SERVICES

The conviction of the original library committee that the library should concentrate on journals rather than on textbooks has been reaffirmed not only by newly appointed members of the committee but also by staff approval. We are now receiving 126 periodicals, of which 6 are gifts to the library. Represented among our journals, in addition to the recognized

Pathologist (Dr. Rosahn) and Medical Librarian (Mrs. Karpman), New Britain General Hospital.

[1] Rosahn, P. D., and Olmstead, M. V. O.: The Medical Library of the New Britain General Hospital, Connecticut M. J. **12**: 23, 1948.

[2] The following persons have served on the library committee: Dr. H. Bellach, Dr. A. J. Canzonetti, Miss A. E. Mooth, R.N., Dr. P. D. Rosahn, Dr. D. E. Wilson, Miss V. Duxbury, R.N., Dr. H. M. Clarke, and Dr. V. J. Squillacote. The first five listed here constitute the library committee at this writing.

periodicals covering the various clinical specialties of medicine, nursing, and dentistry, and also of hospital administration, are many others in the various basic sciences. An attempt has been made to supplement our journals with accredited textbooks covering the different medical specialties, but preference has consistently been given to journals. Accessions for the year ending Sept. 30, 1951, comprised 199 bound volumes of periodicals and 52 textbooks. Our inventory on this date included 1,677 bound volumes of periodicals and 1,239 textbooks. All our journals now have running files of bound volumes dating back for a minimum of five years.

The books and journals in our own library have been supplemented by interlibrary loan material borrowed from many generously cooperating organizations. Among these are the Yale Medical Library, the American Medical Association, the Armed Forces Medical Library, the Hartford Medical Society Library, and the New Britain Institute Library. In the year ending Sept. 30, 1950, for example, the following interlibrary loans were made: 91 bound journals, 52 current periodicals, 13 textbooks, 84 films and slides, 10 pamphlets, 2 microfilms, and 4 photostats and 12 paintings for display on the library walls.

All the libraries mentioned have been extremely helpful in supplying us with material not in our inventory, but special mention should be made of the Yale Medical Library, our principal source of interlibrary loan matter. We early profited by the counsel of the librarian and staff of that great institution, and they have continued to provide us generously with help and guidance. Through our institutional annual contribution to the Associates of the Yale Medical Library, we have attempted to give tangible if modest expression of our appreciation for the interlibrary loan service that the Yale Medical Library has given us.

CLASSIFICATION SYSTEM

It has been our experience that current periodicals, bound or unbound, are easily located on the shelves when arranged in alphabetical order according to the first important word of the title. We have not found it necessary to classify journals according to subject, but this can easily be done in the future if expediency demands such a classification.

At the time of organization of the library, all the major classification systems were reviewed in order that we might determine which would most suit our requirements. These systems have their individual merits, but it was decided that the Cunningham System was the best for our needs, and it was therefore adopted. Subsequent experience has indicated that the Cunningham System, because of its elasticity and simplicity, is ideally designed for a library of our size and type.

ATTENDANCE AND CIRCULATION

The value of a library is not in the amount and variety of material it contains, in the spaciousness of its quarters, or in the cost of its maintenance, but rather in the use to which it is put. Our library has become the foundation on which a vigorous residency training program has been built. Moreover, it has provided a stimulus to our medical and nursing staffs in their desire to maintain familiarity with the current literature. During the 1950-1951 fiscal years there were 867 recorded visits by members of the medical staff, 784 visits by nursing personnel, and 666 visits by others. In addition, there was an unknown number of visits by persons who did not sign our visitors' daily record. In the same year, the following items were borrowed: 421 current periodicals, 169 bound journals, and 657 textbooks. These visits and loans were without doubt important factors in maintaining high medical standards in the hospital.

But more specific benefits accrued to those of our medical staff who were preparing for specialty board examinations. Twelve members of our resident and general staff successfully took these examinations within the past three years. All of them prepared for the ordeal with the help of material in our own library and through our interlibrary loan arrangements. In no instance was it necessary for these physicians and surgeons to spend valuable time and energy traveling to distant places for their library needs.

In the earlier report already mentioned, it was indicated that there are extant two basic conflicting attitudes in library policy. With rigid custodial supervision, and restricted circulation of textbooks and journals for outside reading, a minimum of losses may be expected to accrue. On the other hand, where custodial care is only incidental, and where free withdrawal of library material is permitted and encouraged, the library content receives wide circulation, but losses of many items may be anticipated. The library committee was of the opinion that it was more desirable to have wide circulation with its accompanying probable losses than to have limited circulation and no losses. Accordingly, a liberal policy was adopted, by which access to the library was permitted every day round the clock, even in the absence of the librarian, and at all times library material other than reference books and encyclopedias could be withdrawn. This policy has been happily rewarded, for we have incurred no losses during our five years of operation.

COMMUNITY SERVICE

The only medical library in the city of New Britain is located at the General Hospital. Since many professional persons active in the community in medical and allied fields do not have hospital appointments, it was early decided to invite them to use the facilities of the hospital library. Retired physicians, city-employed physicians, industrial physicians, dentists, nurses, and the faculty and students of the State Teachers College have been encouraged to use the resources of our library. This doctrine of a community medical library, organized and maintained at the local community hospital, is another example of the many services other than the care of the hospitalized sick that a hospital can render to the community in which it is located.

MEDICAL LIBRARY POLICIES

The following library policies are being pursued at this writing:

1. The medical library consists of a main library and a library annex. The main library is located in the basement of the main hospital building and consists of a reading room and stack room, with additional storage space across the hall from the main quarters. General reference books, medical journals and books, and bound or unbound periodicals to be issued on a loan basis are housed in the main library. The library annex is located in the nurses' residence and comprises reference volumes and other material that may not be borrowed. The annex also provides space for storing bound journals dating back more than 10 years.

2. The main library is intended for use by all professional personnel connected with the hospital. This includes physicians, dentists, nurses, dietitians, physical therapists, technicians, and social workers. Members of these professional groups in the community, not officially connected with the hospital, are also invited to use the library facilities, with loans made at the discretion of the librarian.

3. The library annex is for the convenience of the nursing staff. It is unsupervised and is open at all times.

4. The main library is open and the librarian is on duty on Monday through Friday from 8 a. m. to 4:30 p. m. and on Saturday from 8 a. m. to 12 noon. It is closed on Sundays and on all legal holidays officially observed by the hospital. During the hours when the main library is officially open, it may be used both as a reading room and for the issuance of loan material.

5. During the hours when the library is officially closed, the key may be obtained from the admitting office if signed for and returned promptly after the user leaves the library.

6. All books and periodicals taken from the main library must be charged. When the librarian is off duty, a self-charging system is permitted. The borrower fills out a loan slip and drops it into the depository provided.

7. With the exceptions noted below, books and bound periodicals may be borrowed for two weeks and may be renewed for another two weeks, provided they have not been requested by another reader. If, during the period of renewal, they are requested by another reader, they are subject to recall at once. If a volume that is on loan is needed for a reserved shelf, it may be recalled before the limit of the loan period. The latest bound volume of a journal may be borrowed for one week only.

8. Reference books, such as systems of medicine and surgery, bibliographies, indexes, dictionaries, encyclopedias, current periodicals (latest issue received), and books on the "new book table" may not be taken from the library under any circumstances.

9. Unbound periodicals, books reserved for special courses, and reference books (except those restricted under paragraph 8) may be borrowed for overnight use only, i. e., after 4 p. m. Monday through Friday and after 11 a. m. Saturday. They must be returned to the library by 10 a. m. the following morning. Such material taken out Saturday must be returned by 10 a. m. Monday. When the library is officially closed, one may return books and periodicals by using the drop boxes provided in the staff room and at the main library entrance.

10. If a book or journal is lost, the borrower will be taxed the cost of replacement.

PERIODICAL SUBSCRIPTION LIST

Much thought was originally given to the selection of journals. Any newly published journal is reviewed by the library committee, which decides whether or not to add it to our subscription list.

THE HOSPITAL MEDICAL LIBRARY

A library is a living organism. To survive it must be generously nurtured, carefully guided, and constantly tended. A library consisting of randomly selected books and journals, housed on a few dusty shelves, in inaccessible, cheerless quarters, an undeveloped, unused and uninspiring library, is a dead library. A quiet and respectful interment, as befits the honored dead, should be its generous reward. A library proudly supervised, judiciously enlarged through carefully chosen acquisitions, groomed, culled and cultivated, is a living library. Such a library provides knowledge and sustenance to those who seek its haven.

How can the average hospital acquire such a library? Money is necessary, yes. Money provided by the staff, by nurses, and by the administration. But above and beyond the need for money, there must be the deep conviction by medical staff and by administration, that no other single use of funds will so measurably improve the medical standards of the institution. Such a conviction does not arise *de novo.* One or more dedicated souls, members of the staff, must, by discussion, persuasion, exhortation, and conciliation, strive to engender this concept in both staff and administration. Once this has been accomplished, the library is secure.

92 Grand St.

MEDICAL MOTION PICTURES

Journey to Reality: (PMF 5116C) 16 mm., black and white, sound, showing time 40 minutes. Produced in 1951 by the United States Army. Procurable on loan from Area Surgeon of the Army Area in which the request originates.

This film points out the value of prescribed occupational therapy and shows the need for cooperative efforts between psychiatrists and occupational therapists as well as other ward personnel. A number of condensed case histories are given and the various therapeutic approaches illustrated by excerpts from the patient's daily activity. For example, the overactive manic patient is put at a loom, which allows her to expend considerable energy along useful channels; the hostile patient is encouraged to "make his own choice" in the metal shop, where he can work off feelings by pounding; the retarded and depressed patients are given simpler, less taxing activities.

A more descriptive title for this film might possibly have been "The Beginning of the Journey to Reality," since the span of the patients' total program is presented briefly, both in terms of time and of things to be done. Some of the case history portrayal is a bit strained and unrealistic. The medical aspects of the program are well presented. The photography and narration are well done. Its greatest usefulness would be for the orientation of hospital personnel generally and in particular occupational and physical therapists and psychiatric social workers. It could also be used in beginning courses for occupational therapists. Physicians interested in psychiatric problems would also be interested in this film.

BUREAU OF LEGAL MEDICINE AND LEGISLATION

MEDICOLEGAL ABSTRACTS

Charitable Hospitals: Liability for Burns to Child of Pay Patient.—The plaintiff, an infant, filed suit for damages for burns alleged to have been caused by the negligence of the servants of the defendant hospital. The plaintiff was placed in a bassinet immediately after her birth, and a hot water bottle was also placed therein to keep her warm. About two hours later, after removal to the nursery, she was found to have burns on her head and body. The defendant hospital made a motion for a summary judgment in its behalf on the ground that it was a charitable hospital and therefore free from liability in this case. The motion was heard by the superior court, Newcastle, Del.

The question of whether a nonstock, nonprofit, charitable corporation, which conducts and maintains a hospital by public and private contributions and funds received from those who are able to pay, is liable for injury to a patient caused by the negligence of its agents and employees, such as nurses, has never been decided in this state, said the court. It is an important question, and many decisions have been rendered on it by the various courts throughout the country. These decisions are not only conflicting but many of them are also accompanied by dissenting opinions. After discussing the history of the liability and nonliability of charitable institutions from 1846 to the present time and after citing numerous cases considering this question, the court quoted from section 294 of Harper on "The Law of Torts" as follows: "The immunity of charitable corporations in tort is based upon very dubious grounds. It would seem that a sound social policy ought, in fact, to require such organizations to make just compensation for harm legally caused by their activities under the same circumstances as individuals before they carry on their charitable activities. The policy of the law requiring individuals to be just before generous seems equally applicable to charitable corporations. To require an injured individual to forego compensation for harm, when he is otherwise entitled thereto, because the injury was committed by the servants of a charity is to require him to make an unreasonable contribution to the charity, against his will, and a rule of law imposing such burdens cannot be regarded as socially desirable nor consistent with sound policy."

It is contended, said the court, that the overwhelming weight of authority in the United States is in favor of the exemption of charitable corporations from liability for the torts of their agents and employees. After reading many cases decided in the various states throughout the country, the court was convinced that the contention is, at least, doubtful. The numerous distinctions made in the decisions certainly weaken their effect. There is quite a difference, the court continued, between charitable institutions today and those that existed when they were first held to be exempt from tort liability. Those that existed at that time were small and the funds that they had were not large when compared with many that we find today, the funds of which are provided for by foundations and in some instances are unlimited. The argument made in some of the earlier cases, that the funds of the institution would soon become exhausted or that persons would not make donations for charitable purposes if they were used to pay damages does not apply with the same force as it did at that time. There can be no doubt that the trend of decisions today and the views expressed in many of the law journals is in favor of imposing full liability on charitable corporations for the torts of their agents and employees.

Continuing, the court said that it was convinced that the general principle that makes every person responsible for his own legally careless action should apply with equal force to charitable corporations. The doctrine of *respondeat superior* also applies to charitable corporations and makes them responsible for the negligent acts of their agents and employees, when such acts are clearly incidental to the business of the corporation, to the same extent that individuals are. This is true whether or not the beneficiary pays for the service that he receives. It is unreasonable to hold that persons who do not pay for the service that they receive from a charitable corporation cannot recover for injury resulting from the negligent acts of those for whose acts the corporation is responsible when such acts are incidental to the business of the corporation. The court, therefore, held that whether the defendant was negligent by failing to provide proper equipment in the delivery room or nursery of his hospital or whether the agents or employees of the defendant were negligent by failing to properly care for the plaintiff were questions of fact for the jury, but it denied the defendant's motion for summary judgment. *Durney v. St. Francis Hospital, 83 A. (2d) 753 (Delaware, 1951).*

Ethics: Sale of Dental Practice by Widow for Share in Future Earnings.—The plaintiff sued to recover sums paid under a conditional sales contract covering the sale of a dental practice. From a judgment in favor of the defendant, the plaintiff appealed to the Supreme Court of Washington.

The defendant was the widow and executrix of the estate of a deceased dentist and as such became owner of the equipment, accounts receivable, lease, and going business of what was known as "Dr. Conway's Dental Clinic." She entered into a contract for the sale of this asset to the plaintiff dentist. The purchase price was to be $300 a month for ten years, a total of $36,000. In addition, and specifically as payment for the "going business," the defendant was to receive a share of the net profits for the first five years, her percentages to be 70% for the first year, 60% for the second year, and 55% for the following three years. Before any profits were to be divided, however, $300 was to be paid on the purchase price, and the plaintiff was to draw $750 each month, in addition to the payment of all other operating expenses. The plaintiff was taking over an established dental practice with no down payment. The contract with the plaintiff further provided that the defendant would ". . . of necessity dedicate a considerable portion of her time to the protection of her security and advancement of the interest of the business in order that it may return to her the amount contemplated by the parties as purchase price under all of the circumstances now existing." Implementing the above was paragraph 7 providing: "It is further agreed that the doctor shall spend his whole time to the professional care of the office and shall have exclusive control over professional conduct and practice in said office and that the seller shall have the right to be the manager of said business and shall have the right to superintend the business management of the office." Title to fixtures and equipment was reserved to the defendant to secure the payments provided for by the contract; the lease was to be renewed in her name until payment under the contract was complete, at which time it was to become the property of the plaintiff. All new accounts receivable were to be assigned to the defendant during the first five years "as security only."

After the contract had been in force about six months, the plaintiff notified the defendant that the contract was illegal as far as it provided for her participation in the business in any way, and any sums that it was contemplated that the defendant should receive therefor would be illegal. The notice also stated that the books of the clinic would no longer be open to the defendant's inspection or approval and that the defendant was to remain away from the clinic and the employees except for reasonable inspection. In conclusion, the notice said that in the plaintiff's opinion the contract was principally a legal one and that the illegal portions, which contemplated paying the defendant a percentage for management, could be deleted and the management cancelled, but the balance of the contract continued in force.

The Supreme Court said that it could find nothing in the contract to the effect that the percentage payments to the defendant were to be compensation for her management. The contract definitely stated that the percentage of profits she was to receive was "payment for the going business herein contracted to be sold." There was nothing unlawful in the defendant's ownership of the property and interests that she sold to the plaintiff, although, under state law and under decisions of the Washington Supreme Court, the defendant could not have employed anyone to take over her husband's practice and operate it for her. It can not be gainsaid that she had the right to sell that which she owned, either for cash or on terms, and, if on terms, she had the right to protect her interests in any way consistent with the public policy of the state. We have carefully examined the contract, the court continued, and as far as we can determine, it is a bona fide contract of sale calculated to protect and to benefit both parties, and none of the provisions of that contract brand it illegal or contrary to public policy. The fact that the defendant was to have a relatively large percentage of the net profits during the first five years does not establish that she owns, maintains, or operates an office for the practice of dentistry, but rather that she and the plaintiff had agreed on a formula for arriving at a value of the "going business," which we conceive to be the good will of the established dental practice.

The two provisions of the contract that gave the plaintiff great concern are the ones granting the defendant (a) a percentage of the profits and (b) the right to be the business manager and to superintend the business management of the office. It is common knowledge, said the Supreme Court, that many physicians and dentists, and certainly most clinics, leave the details of business records, the issuing of statements, the collection of accounts, and the details of disbursements for supplies and equipment to personnel employed for that purpose, and we do not regard the handling of those details as constituting the practice of medicine or dentistry, although their capable performance may be essential to make that practice profitable. The fact that the same details are supervised by one who, instead of being an employee, is selling the practice under a conditional sales contract does not of necessity constitute such ownership, maintenance, or operation of an office for the practice of medicine or dentistry as is contemplated by the statute, although it could well be a factor requiring a closer scrutiny of the entire transaction to determine whether it is actually what it purports to be or, instead, is a scheme to subterfuge to violate the law. If the plaintiff is entitled to any relief, it is not because the contract is illegal, but because the defendant has exercised a control over the business that constitutes, in fact, the management and operation of a dental office. Some of the conduct complained of by the plaintiff might well be within her rights under the provisions of the contract that were designed for her protection, but, concluded the Supreme Court, the allegations that she "effectuated her control and management of said business by maintaining control of the finances, control of the books, control of the patients, and control over appointments of patients . . .," if true, clearly entitles the plaintiff to relief of some sort.

The plaintiff also contended that the defendant could receive no percentage of the profits, that so long as he paid her $300 a month he was complying with all the legal provisions of their contract, and that he could deny her even an examination of the books. It must be borne in mind, said the court, that the plaintiff did not allege or even suggest that this was not a bona fide sale or that the sale was being used as a blind or pretext to enable the defendant to practice dentistry in contravention of the statute. We are in entire accord with the trial court that the plaintiff cannot recover on the theory that a portion of the contract is illegal. Plaintiff's recovery, if any, must be on the theory that the defendant's conduct so breached the contract as to warrant his abandonment of it, to his damage.

The Supreme Court, therefore, felt that the defendant's demurrer should have been overruled and the plaintiff afforded an opportunity to prove his allegations. The judgment of the trial court in favor of the defendant was accordingly reversed and the cause remanded to the trial court for further hearing. *Prichard v. Conway, 234 P. (2d) 872 (Washington 1951).*

Hexamethonium and *l*-Hydrazinophthalazine in Hypertension.—An antihypertensive drug of only moderate potency, *l*-hydrazinophthalazine, was found to be considerably more effective in patients who had undergone sympathectomy. Malignant hypertension was also found to be susceptible to its action. This suggested that "medical sympathectomy," induced by sympatholytic or ganglionic blocking agents, might enhance the antihypertensive action of *l*-hydrazinophthalazine. It was decided to combine its use with that of a soluble, apparently innocuous ganglionic blocking agent, hexamethonium chloride. Forty patients with chronic arterial hypertension severe enough to require hospitalization, and resistant to dietary measures, thiocyanate administration, surgical measures, and psychotherapeutic procedures were treated. Hexamethonium chloride was usually given in initial doses of 125 to 250 mg. every eight hours, which were increased daily until a maximum of 500 mg. every four hours was reached, or blood pressure showed wide fluctuations, reaching normal levels. At this point *l*-hydrazinophthalazine was added in doses of 25 to 50 mg. every eight hours, in amounts increased by daily increments until a dose of 100 mg. every four hours was reached or the blood pressure had become normal. After normal blood pressure had been achieved in the hospital, a member of the patient's family was instructed in measuring blood pressure; a schedule was arranged for use of the drugs at home, and the patient was discharged. Patients with "benign" arterial hypertension achieved normal or nearly normal blood pressure in every case. Continuous administration was essential for control. In some cases "malignant" hypertension was well controlled with oral doses, while in others it was only partially controlled. The malignant stage was altered favorably in all but two. The method was practical for use at home in intelligent patients. It represents a way of controlling hypertension, but it is not a "cure." Long-term results cannot be evaluated until more time has elapsed. Subsequent experience with 60 patients who have been taking these drugs for from 10 to 28 weeks has shown that 30 have maintained normal blood pressure levels. Of 22 in the malignant stage, 8 have normal blood pressure and 12 slight hypertension; the malignant stage has regressed in all instances. Tolerance to the drugs has not appeared.

Epidemic Histoplasmosis: Follow-up Study.—Histoplasmosis in its acute form occurs either as a benign or as a fulminating fatal disease. It usually appears sporadically, but this paper reports follow-up observations in 1 of 26 cases of diffuse pneumonitis that occurred as an epidemic at an Army camp in 1944 and were reported as cases of "an unusual pulmonary disease." The acute stage of the disease lasted one week. At this time roentgenographic inspection revealed a diffuse mottling throughout both lung fields. No tubercle bacilli were found, and the Mantoux test gave a negative reaction. The coccidioidin skin test likewise gave a negative reaction. Agglutination tests for brucellosis, tularemia, and typhoid and serologic tests for psittacosis all gave negative results. The reactions to serologic tests for histoplasmosis were also negative. A physical examination of one patient six years later showed no abnormality, but roentgenograms of the chest revealed shadows suggestive of the end-stage of pulmonary histoplasmosis. A skin test with histoplasmin gave a strongly positive reaction (4+), while reactions to coccidioidin and Mantoux tests were negative. A complement-fixation test for histoplasmosis, using the yeast phase antigen of Histoplasma capsulatum, was positive to a titer of 1:140 and negative for other fungi. Observations on this patient suggest that the other members of the group thought to have an unusual pulmonary disease also had a benign form of pulmonary histoplasmosis. The authors mention four similar epidemics, the cause of which has never been established. It is hoped that this report will stimulate further follow-up study in these cases.

Leptospiral Meningitis.—Only three strains of Leptospira (Lept. icterohemorrhagiae, Lept. canicola, and Lept. pomona) have been identified here. Although cases of Weil's disease (spirochetal jaundice) have been recognized in various parts of the country, there is reason to believe that the incidence of leptospiral infection is probably greater than is appreciated. The authors searched for evidence of leptospirosis in patients with "benign aseptic meningitis." Positive results were obtained in 6 of 35 patients admitted to one Atlanta hospital during a two year period. A seventh patient was observed in another Atlanta hospital during the same period. Serologic tests for evidence of leptospiral infection were made on approximately 500 pairs of serums obtained from other localities in the United States. These had been submitted to other laboratories for serologic tests for neurotropic viral infection. It was known, however, that many of them had been collected during epidemics of mumps, poliomyelitis, and encephalitis. Leptospiral agglutinins in titers of probable significance were found in 17 instances. Data on these 24 patients permit the following statements: 1. Leptospiral meningitis occurs in many parts of the United States. 2. The clinical features resemble those of meningitides of viral origin, such as mumps, lymphocytic choriomeningitis, and nonparalytic poliomyelitis. 3. Ten of the 24 cases occurred in the month of August. 4. The disease is commoner in males below the age of 30. Laboratory procedures for the diagnosis of leptospiral infection are described.

Antituberculous Properties of Hydrazines of Isonicotinic Acid.—Preliminary observations on two hydrazines of isonicotinic acid ("rimifon" and its isopropyl derivative, "marsilid") indicate that they have tuberculostatic and tuberculocidal action in vitro and a beneficial effect on animals infected experimentally. Parenteral administration of 10 mg. of "marsilid" twice daily (approximately 35 mg. per kilogram of body weight daily) was tolerated well by guinea pigs for 60 days; up to 35 mg. per kilogram daily of "rimifon" was tolerated well for six weeks. Tolerance tests for oral administration to guinea pigs showed that doses up to 40 mg. per kilogram daily of both "marsilid" and "rimifon" were tolerated well for two weeks. Intramuscular tests with rabbits showed good tolerance for 70 days with doses of 30 mg. twice daily (20 mg. per kilogram daily) of "marsilid," and for 21 days with doses of 15 mg. twice daily (9 mg. per kilogram daily) of "rimifon." Guinea pigs infected subcutaneously with virulent human tubercle bacilli and treated with "marsilid" 21 days later revealed very little evidence of tuberculosis grossly when killed 73 days after infection. Thirty days of treatment produced marked changes in the tuberculin skin reactions, which were positive at the beginning of therapy. Five guinea pigs infected by the intracerebral method, which is rapidly and uniformly fatal in untreated animals, were treated with "marsilid" and remained well during 60 days of treatment; since treatment was stopped, 4 have died and the fifth is showing progressive paralysis of the hindquarters. Rabbits infected intravenously with highly virulent bovine tubercle bacilli and treated with "marsilid" for 71 days remained well and failed to develop miliary pulmonary lesions demonstrable by roentgenography. Discontinuance of treatment, however, was followed by relapse of tuberculosis within 10 weeks.

Lesions of the Small Intestine.—Sawyer and Lubchenco feel that too few lesions of the small intestine are diagnosed before operation or autopsy. They summarize their experience in treating 26 inflammatory and neoplastic lesions involving the jejunum and ileum. Lesions proximal to the ligament of Treitz and congenital anomalies were not included. The 13 patients with inflammatory lesions included 8 with regional ileitis, which is a nonspecific chronic recurrent granulomatous disease characterized by a necrotizing, ulcerating, inflammatory process. Abdominal pain, diarrhea, and secondary anemia are the cardinal features. Further confirmation of the diagnosis can be obtained from the roentgenographic recognition of the string sign. The treatment of choice is resection of the involved ileum and the right side of the colon with end-to-end ileotransverse colostomy. There were two patients with tuberculosis of the small intestine, two with diverticulitis, and one with periarteritis nodosa. The seven patients with benign neoplasms included two with carcinoid, two with endometrioma, and one each with lymphangioma, leiomyoma, and lipoma. Five of the six malignant lesions were carcinomas and one was a lymphoma. Carcinoma is the commonest malignant tumor of the small intestine. The symptoms are usually related to perforation, bleeding, or obstruction. The authors stress that any patient with unexplained diarrhea, intestinal bleeding, or abdominal pain should be subjected to careful clinical and roentgenologic study of the small intestine. Examination of the entire small intestine during routine laparotomy is worth while, and frequently reveals the pathological condition responsible for the patient's complaints.

Priscoline® Intra-Arterially in Vascular Disturbances.—If priscoline® (2-benzyl-4,5-imidazoline) hydrochloride is injected rapidly into the regional artery of the human limb, an increase in blood flow can be observed through the main arterial channels, in the blood vessels of the skin, and throughout the deep tissues of the extremity. This effect lasts only a few hours, but after a series of injections it becomes more sustained. At a Bronx, N. Y., hospital 76 patients with peripheral vascular disease were treated by intra-arterial administration of priscoline.® In 11 patients who had gangrene of the heel, the lesions of 8 healed and 3 had to undergo amputation. This compares favorably with a control group of 11 cases in which 9 patients had to undergo amputation. Of 49 ischemic lesions in other parts of the extremities, 23 healed, and in 26 cases intra-arterial therapy was ineffective. In two of seven cases of acute arterial occlusion, embolism was the cause, and both of these patients recovered without trophic lesions; of the five who had thrombotic occlusions, two required an amputation. Four cases of iliofemoral thrombophlebitis with spastic arterial occlusion rapidly improved with one or several intra-arterial priscoline® injections. In four patients with intractable Raynaud's disease attacks disappeared during and for some time after intra-arterial priscoline® therapy, the noninjected arm serving as a control. In five cases of functional vascular disturbances, intra-arterial administration of priscoline® had a temporary and localized vasodilator effect. Priscoline® is injected rapidly into the artery in amounts just short of systemic reactions. The most effective injection schedule must be determined individually. The goal of intra-arterial priscoline® therapy in peripheral vascular disease is a sustained (not always maximal) vasodilatation in the extremity. This is maintained by regular injections over a period of days or weeks. Interruptions of the schedule or a clumsy injection technique that produces pain and vasoconstriction may prevent sustained vasodilatation. Contraindications to intra-arterial priscoline®

therapy are systemic reactions after intra-arterial injections of 10 mg. of priscoline® or less, a temporary decrease in local blood flow or edema, and skin maceration in an ischemic area after intra-arterial injection. Intra-arterial injection of this drug is a useful diagnostic test similar to a posterior tibial or lumbar sympathetic nerve block, and, carefully used, may be a valuable adjunct to treatment of peripheral vascular disorders.

Dangers of Bishydroxycoumarin.—From clinical observations and from experiments on rabbits Martorell deduced that the effective antithrombotic dose of bishydroxycoumarin (dicumarol®) and the hemorrhage-producing dose are too nearly the same. Although this drug has the advantage of being administered orally, its therapeutic efficacy is doubtful and the danger attendant on its administration reaches such proportions that it should be asked whether the risk is less for the patient from pulmonary embolism, which is not necessarily a complication of venous thrombosis, or from death by hemorrhage caused by the drug even under the most favorable conditions and with the most rigorous control of the prothrombin index.

Pathogenesis of Postirradiation Anemia.—The hemolytic effect of large doses of irradiation is well established; the objective of this study was to determine whether irradiation within the lethal range injures erythrocytes in vivo. One group of rabbits was injected with radioiron-tagged erythrocytes shortly before exposure to 800 to 1,000 r and another group immediately after irradiation. A control group received the tagged erythrocytes but no irradiation. There was a drop in red cell mass in both irradiated groups as compared with the controls, but there was no difference between the two irradiated groups, i. e., between the behavior of irradiated and nonirradiated erythrocytes in irradiated hosts. These findings indicate that there is no direct effect of irradiation in the median lethal range on erythrocytes in vivo. It requires nearly lethal doses of x-rays to cause conspicuous anemia. In the fatally irradiated animals the drop in red cell mass and total circulating radioiron is precipitous; in those nonfatally irradiated the drop is gradual and relatively slight, even though the animals may have received the same dose. Increase of specific organ activity of the liver and spleen of irradiated animals can be correlated with hemosiderin deposits and congestion. Deposition of hemosiderin is a consequence of irradiation, its degree increasing with the effectiveness of the irradiation. In rabbits the erythrocyte masses obtained by two direct isotopic techniques (P^{32} and Fe^{59}) and by one indirect technique (T-1824 dye) differ by constant ratios. The Fe^{59}:P^{32} ratio is 0.89; the Fe^{59} values are regarded as correct. With the aid of conversion factors either technique can be used. If an indirect technique is employed and the erythrocyte mass is estimated on the basis of plasma volume measurements, it is necessary to calculate first the average body hematocrit value. This is done by multiplying the large vessel hematocrit by a conversion factor, which is 0.83 in normal rabbits. The authors conclude that irradiation at or below the median lethal dose does not hemolyze erythrocytes directly, but some change caused by massive irradiation results in increased destruction of erythrocytes. It is postulated that this change is damage to the capillary wall causing diversion of erythrocytes into tissue spaces and lymphatics, resulting in injury of some erythrocytes. Thus, the anemia of irradiation is in part relative, in part absolute.

Effects of Diet and Choline on Fatty Infiltration of Liver.—This report is based on studies of 17 alcoholic patients with fatty infiltration of the liver. They were hospitalized, and clinical observation, liver function tests, and needle biopsies of the liver were made. They were placed on dietary schedules, and at intervals of 3 to 15 weeks the liver biopsies were repeated. The histological specimens were graded 0 to 4 plus for fat, periportal lymphocytic, and fibrous infiltration. Liver function tests were checked biweekly. These patients were not critically ill. Some were malnourished, others had jaundice, and all were in the state usually observed after cessation of excessive alcohol intake. One group of patients received the regular hospital diet of 250 gm. of carbohydrate, 75 gm. of protein, and 75 gm. of fat, supplemented with vitamins of the B complex group in a few cases, because of peripheral neuropathy and glossitis. A second group of patients was offered this diet, but the patients ate poorly and continued to drink heavily, through clandestine measures. A third group received the aforementioned diet to which choline was added. The basal diet had significant lipotropic effects in 13 patients. The ingestion by four patients of 4 to 17 gm. of choline bicarbonate with the basal diet did not increase the lipotropin effects observed with the diet alone. Continued ingestion of alcohol with poor dietary intake prevented the disappearance of fat from the liver. Thus the studies demonstrated that with intake of approximately 1 gm. of protein per kilogram of body weight effective lipotropism occurs within four weeks. Addition of two to six times as much choline as had been used previously had no added demonstrable effect, either on the clinical appearance of the patient, the liver function tests, or the cell structure of the liver.

Corticotropin (ACTH), Cortisone, and Pregnenolone in Collagen Diseases.—Pregnenolone, cortisone, and corticotropin (ACTH) were given to 250 patients with a collagen or allied disease. Effective initial doses ranged from 400 to 1,000 mg., 75 to 150 mg., and 80 to 120 mg., and maintenance doses from 200 to 400 mg., 25 to 50 mg., and 20 to 40 mg., respectively. In patients with rheumatoid arthritis complete remission was obtained in 10 of 40, 4 of 12, and 4 of 5 patients treated with pregnenolone, cortisone, and corticotropin, respectively. The effect of cortisone and corticotropin on the joint disturbances was much greater than that of pregnenolone, which affected only the periarticular and psychic manifestations of the disease. In patients with gout both corticotropin and cortisone were superior to pregnenolone, bringing about a quicker and more complete action. In patients with acute and chronic lupus erythematosus pregnenolone seems useless; cortisone, though valuable, may fail; and corticotropin will bring amelioration and remission. Cortisone and corticotropin were equally useful in psoriasis, scleroderma, uveitis, and asthma, whereas pregnenolone had some effect in scleroderma and psoriasis. Of 31 patients with osteoarthritis, 16 obtained considerable improvement with pregnenolone in the periarticular structures. There was a decrease in muscular spasm, and an increase in mobility but no alteration in the joint lesion itself. None of the drugs appeared to influence the articular disturbance. From the clinical point of view, the temperature becomes normal rather rapidly and abruptly with cortisone and corticotropin, whereas with pregnenolone it is not influenced in lupus erythematosus, and in the other diseases it becomes normal more or less by lysis. Cortisone and corticotropin produce eosinopenia in patients in whom they are useful, while pregnenolone does not. With cortisone and corticotropin euphoria is pronounced, and, if the drugs are administered too long, the patient may show irascibility, despondency, and true psychotic manifestations. These untoward effects on personality are avoided with prolonged use of pregnenolone. Undesirable side-effects appeared in 3 of 211 patients treated with pregnenolone, 13 of 41 treated with cortisone, and 6 of 26 treated with corticotropin.

Pathogenesis of Tinea Capitis.—The data reported in this paper were derived from work carried out at a state institution for congenital mental defectives where tinea capitis was endemic. A large number of persons living under confined circumstances could be inoculated, and the course of the disease minutely studied from its onset. In inoculations of the human scalp with Microsporum audouini and M. canis it was found that some form of minor trauma was a prerequisite for infection. About 60% of children were found to be susceptible to experimental tinea capitis due to M. audouini and M. canis. Although a somewhat smaller percentage of adults could be infected with M. audouini, the disease was trivial in this group. Tinea capitis has four phases: (1) an incubation period, (2) a period of enlargement and spread, (3) a refractory period, and (4) a period of involution. Tinea capitis consists of two distinct types of infection: (1) scalp infection, and (2) hair infection. Either may exist alone, and usually both are present in the early phase of tinea capitis. There are probably many persons with an innate resistance to the disease. In a susceptible person infection does not follow simple contact with the spores, which must be implanted into the stratum corneum. Minor trauma is hence a precondition for infection. The lower incidence of infection among girls is probably due to the fact that their long hair helps prevent the spores reaching the scalp surface. Transmission in the barber shop is possible, considering the minor trauma probably incident to combing and clipping. Boys who rub the backs of their heads against infected theater seats also are subjected to ideal circumstances for acquiring the infection. It might be assumed that the exclusion of infected children from barber shops and theaters would contribute substantially to control of this disease.

Simple Excision for Pulmonary Tuberculosis.—Wedge or subsegmental resection of diseased lung areas was done in 30 patients with pulmonary tuberculosis for removal of tuberculous foci that remained after continuous daily treatment with streptomycin and *p*-aminosalicylic acid for four months or longer. Bilateral resections were done in three of these patients. Of the 30 patients, 4 had minimal pulmonary tuberculosis and none of these had shown tubercle bacilli in repeated cultures of sputum or gastric washings during hospitalization. They were operated on because minimal pulmonary tuberculosis always contains one or more necrotic lesions generally localized in the superior or posterior portions of lobes of lung, and it should be possible to remove these lesions completely by a small local excision. Of the remaining 26 patients, 16 had moderately and 10 had far-advanced pulmonary tuberculosis. None had had positive cultures of sputum or gastric contents for many weeks or months prior to surgical intervention. The amount of lung tissue to be excised, usually with disregard for the segmental anatomy of the lungs, was determined after a complete palpation of the lung had been done considering preservation of a maximum amount of functional lung. The wedge to be resected was outlined, the pleura incised a short distance beyond the disease area, and the area excised en bloc. Sutures were applied to bleeding points and bronchial leaks. Each resected specimen showed necrotic pneumonic lesions, and the cavity-bearing areas removed showed filled-in cavities with patent bronchial communications. Otherwise there were areas of scarred tissue, with extremely little evidence of unhealed non-necrotic pneumonic lesions. Postoperative cultures of sputum or fasting gastric contents were negative for tubercle bacilli. There was little change in the cardiorespiratory reserves postoperatively, as compared to preoperative findings. No postoperative tuberculous complications arose. No complications of any sort occurred in the four patients with minimal disease. As a rule, the postoperative course was benign. One year after the intervention all patients are in excellent physical condition. It is recognized that a lapse of five years may be necessary for final evaluation. The authors do not claim that their approach to the surgical problem of the tuberculous lung will eradicate all of the pulmonary disease, but it is anticipated that the small lesions left behind will cause no further trouble. The immediate results have been encouraging enough to warrant continuation of the program.

Bilateral Total Adrenalectomy.—Of 9 selected patients with advanced malignant hypertension and 5 with chronic nephritis, 13 were subjected to bilateral total adrenalectomy by the posterior approach, and one patient with nephritis had one adrenal removed as a first stage procedure. The patients operated on had failed to respond to medical treatment and at the same time their disease was considered too far advanced to be benefited by sympathectomy. A salt-free diet, diminution of edema by diuresis, digitalization, and sedation were fundamental preoperative measures. Additional measures for correction of renal insufficiency and electrolyte imbalance were necessary in four patients, external dialysis being used for one. Cortisone in doses of 100 mg. was given intramuscularly the night before operation and repeated the next morning before surgical intervention. During operation 100 to 200 cc. of aqueous adrenal cortical extract and 20 to 50 mg. of phenylephrine (neo-synephrine®) hydrochloride by intravenous drip was given as required for circulatory stability. Cortisone, 50 mg. every six hours, was given intramuscularly during the first 48 postoperative hours and then was gradually reduced to 25 to 37 mg. per day as a maintenance dose. In the late postoperative care salt depletion must be avoided by adding 3 gm. or more of sodium chloride to the diet and/or 1 mg. of desoxycorticosterone acetate per day three to six times a week as necessary to avoid weakness and hypotension. Two patients died of renal failure and two of cardiac complications of their vascular disease. Nine patients are living after complete adrenalectomy and seven of them are definitely improved both subjectively and objectively. One patient previously incapacitated for three years has been working for six months as a hospital orderly and another has resumed his work as an insurance agent. In their preliminary report the authors attribute the improvement to elimination of natural desoxycorticosterone-like factors and their administration thereafter in such a manner as to avoid excessive retention of sodium and water on the one hand and relative hypotension on the other. It has been shown that absence of the adrenal glands today may be compatible with an active existence, owing to available substitution therapy.

Pulmonary Embolism by Amniotic Fluid.—A total of only about 30 pathologically verified cases of pulmonary embolism and obstetric shock caused by amniotic fluid have been reported. The case described here was that of a woman in whom there had been some bleeding coincident with membrane rupture. Less than two hours later, she complained of difficulty in breathing, and then had generalized convulsions, and became cyanotic, hyperpneic and pulseless. Simultaneously there appeared red blood from the mouth, numerous rapidly spreading ecchymoses on the abdomen, chest, back, arms, and legs, and massive submucous and subcutaneous extravasation of blood involving the vaginal walls, perineum, and inner right thigh. All needle punctures oozed constantly. The placenta was delivered intact following normal separation. Despite administration of whole blood and supportive measures, massive pulmonary edema and coma occurred, and the patient died. This case of pulmonary amniotic fluid embolism has some factors in common with other cases, but differs in respect to the postmortem uterine lesions and the local genital symptoms. No evidence of abruptio placentae, placenta previa or accreta, or deep cervical or placental tear was present, but a large tear was found in the uterine endometrium. The shock was definitely anaphylactoid, and the skin was warm and dry. Unlike the patients in most cases, the patient rallied to a considerable extent from the initial shock. In the presence of afibrinogenemia, even massive transfusion (short of exsanguination and replacement) will be of no appreciable benefit unless fibrinogen is available. Since no distinction can be made in vivo between patients with intravascular fibrin clotting mechanisms and patients with amniotic fluid embolism, treatment of these conditions is essentially the same, and consists of measures to overcome shock, to control hemorrhagic manifestations, and to combat pulmonary edema. The availability of blood and fibrinogen is important.

Cysts and Degenerative Changes in Knee Menisci.—McDermott prefers the term menisci to semilunar cartilages, chiefly because it has been observed that these structures do not assume the characteristics of a cartilage until the age of 15 years. He had available for study a group of 50 menisci. Some of these had been removed because of clinically diagnosed cysts and others because of rupture. The remainder of the menisci were removed post mortem from patients with no evidence of disease of the knee joint, or from human embryos. Theories concerning the etiology, nature, and pathogenesis of the cysts as well as their relationship to rupture of the menisci are discussed. The following conclusions are formulated: 1. Cysts of the menisci result from several types of degeneration of the connective tissue. 2. The cysts have no specialized lining. 3. Synovial membrane is not endothelial in nature. 4. Cysts of the meniscus present histologically resemble ganglion cysts and myxomatous intracutaneous cysts. 5. There is no histological resemblance between meniscal cysts and the synovial membrane to suggest relationship between them. 6. Some of the so-called ruptures of the menisci may well be spontaneous in nature due to a degenerative lesion of these structures. 7. Cysts of the menisci may recur if the entire meniscus is not removed. 8. The relatively greater exposure of the internal meniscus to trauma may explain the greater frequency of rupture of this structure and the greater incidence of cysts in the external meniscus. 9. Trauma has little or no etiological importance in production of degenerative changes and meniscal cysts. 10. The etiology of the degenerative process responsible for the production of cysts of the menisci remains obscure.

Splenectomy in Leukemia and Leukosarcoma.—Eleven of the 18 patients in this series had splenectomy for some type of leukemia, and 7 were found to have leukosarcoma. The decision to remove the spleen was made only after long observation. Nearly all patients had had roentgen therapy over the spleen to the limit of toleration. In leukemia, nitrogen mustard, urethane, triethylenemelamine, adrenocorticotropic hormone, or cortisone had been used. Hypersplenism, as manifested by cytopenic disturbances alone, was present in seven patients; five had severe hemolytic anemia; four had hemolytic anemia and cytopenic hypersplenism; and in two the spleen was removed because of its large size and painful symptoms. Size alone is not a sufficient indication for splenectomy. For the best results of splenectomy in hypersplenism the bone marrow should be hyperplastic. If the patient has required frequent transfusions to control a hemolytic anemia or severe cytopenia, splenectomy may be indicated, but a markedly diminished number of megakaryocytes or nucleated red blood cells in the bone marrow contraindicates splenectomy. Hemolytic anemia or the cytopenic disturbance was controlled for a reasonable period of time in 11 of the 18 patients, 5 patients were not benefited, and 2 died in hospital after operation. In one man, who had been observed for 18 months before operation, severe hemolytic anemia was the indication for splenectomy. Follow-up studies of the peripheral blood revealed that there was complete remission of the hemolytic anemia until death resulted from coronary occlusion. In a patient with pancytopenia, hemolytic anemia, and lymphosarcoma complete remission of the pancytopenia and hemolytic anemia persisted for two years. Another patient who had hemolytic anemia and lymphocytic leukemia responded temporarily to splenectomy. This patient was given a course of corticotropin prior to splenectomy. Other investigators recently reported striking improvement of the hemolytic process following corticotropin therapy in cases of acquired hemolytic anemia. Such treatment should probably be used in every case prior to splenectomy, with operative intervention reserved for patients who fail to respond to medical therapy. While it has been suggested that splenectomy should be performed early in the course of leukemia to obtain the best palliation, these authors do not believe that splenectomy is indicated unless the spleen is extremely bulky and is causing pain. They do not advocate the indiscriminate use of splenectomy, but advise that it should be confined to a small number of specially selected cases.

Mortality and Survival in Cancer of Stomach.—During the years from 1907 to 1949, 9,620 patients underwent operation for malignant neoplasm of the stomach at the Mayo Clinic, and it is estimated that there were in addition about 3,500 seen but not operated on. Of the total of 9,620 operations, 4,597 (47.8%) were resections, 1,327 (13.8%) were palliative operations, and 3,696 (38.4%) were exploratory laparotomies, with respective average hospital mortality rates of 13.3, 12.3, and 3.8%. The survival rates following operation are analyzed with relation to metastases, to grade of malignancy, to gastric acidity, and to sex. In order to ascertain whether the outlook for the patient with gastric cancer has improved, the records of the period 1907-1916 are compared with those of the period 1940-1949. The five year survival rate for the recent period is 35%, whereas for the earlier period it is 29%. The 10 year survival rate for the recent period is 27%, while for the earlier period it is 22%. There has also been improvement in the operability rate, resectability rate, and hospital mortality rate. In the early period, only 5 of 100 patients with gastric malignant lesions could be expected to be living five years later; in the later period the expected number living five years after diagnosis has increased to 14. However, this figure conveys a false idea of the efficacy of surgical therapy, because in the later group 20 of the 86 patients who died within 5 years were found inoperable when they were first examined, and in 36 more laparotomy revealed a lesion that was not resectable. Thus 56 of 86 of the deaths are accounted for by the patient's being seen too late for effective surgical intervention. The other 30 patients can perhaps be considered the true surgical loss, since in spite of surgical effort they do not survive more than five years. If the aforementioned 56 patients should be seen by the surgeon when resection was possible, then without any further improvement in the surgical results, 18 survivors would be added to the present 14, more than doubling the number salvaged out of the original 100. Whether education or better diagnostic methods will accomplish this remains a problem for the future.

Injection Treatment of Internal Hemorrhoids.—The Dodsons evaluate the results they obtained by injection treatment in 697 cases of hemorrhoids. Of the 697 patients, 443 (63.3%) had recurrences within five years, and the authors suspect that the actual recurrence rate was even higher. Of the 201 patients classified as having first degree internal hemorrhoids (bleeding only), 76 (38%) required re-treatment, 62 being subjected to hemorrhoidectomy and 14 to reinjection. Of the 176 patients with second degree hemorrhoids (bleeding and protrusion that is spontaneously reduced), exactly half required re-treatment. Of the 289 with third degree internal hemorrhoids, 140 have had hemorrhoidectomies, 63 have had re-treatment by injection, and 35 with recurrent symptoms refused further treatment but were told that surgical intervention would be necessary for cure. All 31 of the patients with so-called fourth degree lesions have had recurrences. Thus curability by sclerotherapy varies in inverse proportion to the degree of prolapse of the hemorrhoids. Best results of injection treatment are obtained in uncomplicated first degree internal hemorrhoids. Second degree hemorrhoids are sometimes adequately treated by injections, but in third degree and fourth degree cases only temporary and usually incomplete results can be expected. At best, the recurrence rate with injections far exceeds that of careful surgical treatment. For cases in which surgical treatment is contraindicated or refused, sclerotherapy is a useful palliative measure.

Normal Young Men Treated with ACTH and Cortisone.—Side-effects of corticotropin (ACTH) and cortisone were studied in young combat veterans with frostbite injuries that healed with medical care in all but one instance. Corticotropin (20 mg. in 1 liter of 5% dextrose in water or sodium chloride solution or in isotonic sodium chloride solution alone) was given to 13 patients daily over a six hour period for 31 consecutive days. Cortisone was given to 22 patients by mouth as follows: 400 mg. (100 mg. every 6 hours) for 1 day; 300 mg. (75 mg. every 6 hours) on the second day; 200 mg. (50 mg. every 6 hours) until the 12th day at which time 200 mg. (100 mg. at 8 a. m. and 8 p. m.) was given daily through the 31st day. There was a control group of 26 patients. Four patients (two in each hormone therapy group) were placed on moderate fluid and candy intake; otherwise, diet was unrestricted and contained excessive quantities of candy bars and soft drinks. There was no significant difference between the groups in regard to personal or familial illnesses, length of time in combat, or previous combat wounds. The side-effects noted in order of frequency were moon face, glucose intolerance, hypertension, acne, hirsutism, edema, and psychic changes. No untoward reactions were observed during intravenous administration of corticotropin, whether it was given slowly or rapidly. The effects of cortisone given orally did not differ from those obtained with intramuscular administration; no untoward gastrointestinal manifestations were noted. At least one side-effect was found in 83% of the group receiving hormone therapy; only in one case was the side-effect severe enough to force discontinuance of the treatment. Side-effects occurred in 43 patients who were given cortisone and in 17 who were given corticotropin. All the side-effects disappeared after the hormone treatment was discontinued; their common occurrence in essentially normal young men indicates pharmacologic effects, with moderate individual variation depending on dosage and duration of therapy rather than significant variation in end-organ response.

ACTH Intravenously in Treatment of Shock.—Corticotropin (ACTH) administered intravenously in three cases of apparently irreversible shock produced such rapid responses that they are made the subject of a preliminary report. The adrenocortical hormones are essential factors in the normal balance of organic functions, and enable the body to meet and overcome stress. Sudden exhaustion of the adrenocortical steroids and loss of their action on the vasomotor tone may be important in the onset of shock. Intravenous administration is apparently a safe, effective, and economical method of giving corticotropin, and has been used in various conditions. Corticotropin and cortisone have heretofore been used for shock following burns and in two cases of the Waterhouse-Friedrichsen syndrome. Intravenous use of corticotropin for serious shock is a new method, and the rapidity of the response obtained indicates that corticotropin has an immediate and selective action on vasomotor tone. The patients treated, all of whom were undergoing serious surgical procedures, had received the usual remedies for shock without showing any favorable response; all three were moribund. Administration of 40 mg. of corticotropin in 500 cc. of isotonic sodium chloride solution at a rapid rate (120 drops a minute) was quickly followed by return of the pulse, which had been imperceptible, restoration of arterial pressure, and resumption of normal breathing. All three patients recovered and were discharged from the hospital. No permanent neurological sequelae were noted; but in one case an excessive dose of corticotropin, made necessary by recurring signs of shock, led to temporary hypercorticism that was rapidly dissipated when administration of the drug was discontinued.

Acute Cardiac Infarction Without Pain.—Acute cardiac infarction without pain is rare. In 150 cases in which coronary thrombosis with electrocardiographic signs of acute cardiac ischemia was diagnosed, Papp found seven patients in whom pain was completely absent, and in an eighth patient slight pain was present for a short time only. Three of the eight patients had congestive heart failure with cardiac infarction. Two died and at necropsy were found to have extensive arteriosclerotic heart disease with occlusion of more than one main coronary artery. The third, who survived, had a slight cardiac infarction during an attack of cardiac asthma. Acute paroxysmal dyspnea was the main symptom in all; this may overshadow coronary pain. Five patients had complete heart block during the attack. Four of them had no pain; in the fifth, who had intermittent heart block, pain appeared when normal rhythm was restored. Complete heart block was recorded in four, and lasted from one and a half hours to one week or more. The electrocardiogram indicated posterior infarction in three, anteroseptal infarction with right bundle branch block and later left bundle branch block in one, and anteroposterior infarction in one. All patients recovered; one had a small anterolateral infarction accompanied by pain, but not by heart block, 18 years later, from which he also recovered. Faintness with a pulse rate of 30 to 40 was the main clinical symptom, but complete loss of consciousness occurred only in one patient. These attacks differ from classical Stokes-Adams attacks in that ventricular standstill, ventricular tachycardia, and therefore complete loss of consciousness may be absent. Sudden fall of pulse rate accompanied by fall of blood pressure, as it occurs in complete heart block during acute cardiac infarction, may induce incomplete cerebral anoxemia; this causes faintness without loss of consciousness, but with loss of sense of pain. Prognosis is serious in cardiac infarction without pain and complicating heart failure; with complete heart block it may be less serious than is generally accepted, since transient block may be a sign of only temporary ischemia of the conducting system.

Incidence of Pulmonary Embolism.—During the past decade it has been realized that most pulmonary emboli are not massive and fatal, and that they concern internists at least as much as surgeons and obstetricians. Indeed, the present study suggests that thromboembolic disease of the lung may have become the commonest of serious acute pulmonary lesions seen in general hospital practice. Pulmonary thromboembolism was diagnosed in 120 patients in 30 months, of whom 113 were in the wards of a general hospital. The incidence of pulmonary thromboembolism in this hospital was higher than that of lobar pneumonia. Pulmonary embolism was directly responsible for 30 deaths, and pulmonary infarction was an important contributory factor in 13 more. Seventy of the 120 cases were classed as medical, and four-fifths of the patients had heart disease. There were three instances (one fatal) of pulmonary embolism appearing without warning in apparently healthy subjects. In 4 of the 30 surgical cases (8 fatal) pulmonary embolism occurred when the patient first got out of bed. Among the 20 obstetrical cases (2 fatal) pulmonary embolism was nearly three times as common in those over the age of 30 as in those under 30. Pulmonary embolism was seen only once in the absence of obvious femoral thrombosis or some complication of pregnancy or delivery. Pleuritic pain and hemoptysis are the two most striking symptoms of pulmonary infarction. Pleuritic pain was noted in 65% of all cases, and was present in 90% of the surgical and obstetrical cases. Hemoptysis was noted in less than 40% of all cases. The physical signs in the chest of pulmonary infarction depend on three factors, namely, consolidation, pleurisy, and elevation of the diaphragm. Signs of pleural effusion were present in one-fifth of cases. The fluid was blood-stained in 8 of 17 cases in which it was inspected. Jaundice was observed in almost one-third of the cases of heart disease complicated by pulmonary infarction. A paroxysm of auricular fibrillation was precipitated by pulmonary infarction in five cases. In several patients with congestive heart failure the symptoms were slight, and the presence of pulmonary infarction was overlooked. In postoperative and puerperal patients the condition was often misdiagnosed as pleurisy, pulmonary collapse, or pneumonia.

Deafness from Dihydrostreptomycin in Tuberculous Meningitis.—The results obtained in 26 cases in which streptomycin was administered were compared with those in 51 cases in which dihydrostreptomycin was given. Two-thirds of the patients treated with dihydrostreptomycin recovered, and one-half of those treated with streptomycin. While half of the survivors treated with dihydrostreptomycin were deaf, only 1 of 13 survivors in the streptomycin series had impaired hearing.

*Splenectomy in Therapy of Subacute Bacterial Endocarditis. K. Fellinger and W. Weissel.—p. 499.

Surgical Treatment of Mitral Stenosis.—The aim of the surgical treatment of mitral stenosis is not only to overcome the stenosis but also to preserve the closure function of the mitral valves. In the mild form of endocarditis, the stenosed orifice is usually a narrow oval, the classical button-hole stenosis, whereas in the severe form of endocarditis, the orifice is not oval, but round, irregular or triangular. Surgical correction of mitral stenosis is effected by splitting the margins of the coalescent cusps in the line of the former axis, that is, in the commissures. The authors mention Bailey, Brock, Harken, and O'Neill as having described techniques of commissurotomies or valvulotomies, and say that splitting is done most effectively with the finger equipped with a special knife, the finger being the basic instrument. Splitting of the commissures not only counteracts the stenosis but also produces functioning valves capable of closure. Injury to the valves outside of the commissures must be carefully avoided, because surgically produced defects in the valves may impair their closure. After commenting on several other problems, particularly the danger of postoperative acute mitral insufficiency, which may be brought on by the reduced tolerance of the left ventricle, the authors describe observations on seven patients in whom they performed operations for mitral stenosis. The patients ranged in age from 18 to 45 years. All patients experienced objective improvement, including those who had had decompensation for a long time and who had the corresponding anatomic and clinical changes. Severe myocardial lesions, even those in the region of the overloaded, hypertrophied and dilated right ventricle, and absolute arrhythmia after embolism, are not contraindications to the operation. It is essential, however, that no florid endocarditic process exists.

Splenectomy in Subacute Bacterial Endocarditis.—Although splenectomy was used in treatment of subacute bacterial endocarditis long before effective antibacterial therapy by means of antibiotics had become possible, now it is resorted to occasionally as an additional measure and in cases in which the antibiotics prove ineffective. In the 11 cases analyzed in this paper, splenectomy was done after treatment with antibiotics had failed. Clinical cure followed splenectomy in three of these cases, and in two others cure followed later, the fever subsiding only after a course of streptomycin, which had not been tried before splenectomy. The six other patients died despite splenectomy, but in one of these cure of the endocarditis could be proved by autopsy. There was no primary surgical mortality in these cases. Thromboembolic complications were not increased by splenectomy; at any rate, in the cases described here, the increase in thrombocytes that followed splenectomy did not result in thromboembolism. Even renal insufficiency is not an absolute contraindication to splenectomy. The time at which splenectomy is done seems important for the success of this measure, operation having been done in the successful cases during or after the first attack or relapse. However, the patients in whom splenectomy had proved successful had also received more penicillin and streptomycin. The authors make some suggestions on the possible mode of action of splenectomy, but complete clarification will require further observation and investigation.

Kidney and Hypertension. E. Randerath and A. Bohle.—p. 517.
Prognosis of Acute Diffuse Glomerulonephritis. H. Sarre and H. Mahr.—p. 522.
Humoral Reactions of Blood in Tuberculous Patients. P. Klee, H. Hörlein and K. Jahnke.—p. 525.
*Recovery from Tuberculous Meningitis with Combined Treatment with Streptomycin and *p*-Aminosalicylic Acid in 90% of 36 Cases. W. Löffler, S. Moeschlin and H. Zollikofer.—p. 542.
*Behavior of Intestine Following Treatment with Chloromycetin. F. Sandmann.—p. 557.

Recovery from Tuberculous Meningitis with Chemotherapy.—Combined treatment with streptomycin and *p*-aminosalicylic acid was employed in 23 male and 13 female patients between the ages of 6 and 54 with tuberculous meningitis. Streptomycin was given intramuscularly in doses of 0.5 gm. twice a day for two months and dihydrostreptomycin, 0.5 gm. daily, for an additional four months. In addition streptomycin was given intraspinally in doses of 100 mg. daily the first week, 50 mg. daily the second to the fourth week, and then 50 mg. three times a week for one month, two times a week for three months, and once a week for two additional months. *p*-Aminosalicylic acid was given by intravenous drip in doses of 40 gm. daily the first week, 30 gm. daily the second to the eighth week, and 12 to 14 gm. intravenously five days a week and orally two days a week for four months. Of the 36 patients who were followed for 3½ to 38½ months, 31 were free of symptoms, 2 were still under treatment, and 3 had died of meningitis. Of the three patients who died, treatment was not started until the 20th day in one, and was discontinued too early in the other two at their own request. Of the 36 patients, 9 had associated miliary tuberculosis and 7 of them recovered. Complete blocking of cerebrospinal fluid, which had been observed frequently in patients treated with streptomycin alone, did not occur in any of the patients, and partial blocking occurred in only one patient in whom combined treatment was started on the 15th day. Bilateral impairment of the vestibular nerve occurred in 12 patients, and severe impairment of the eighth cranial nerve in 3. Of the 34 patients followed for one to three years, 3 died and 31 recovered, an average recovery rate of 90%, the best recovery rate so far recorded for tuberculous meningitis in patients followed for long periods. If one considers only the 23 patients in whom the presence of tubercle bacilli in the cerebrospinal fluid was established by culture, animal experiment, or direct detection, there were only three fatal cases after a one to three years' follow-up. Among the patients who recovered from meningitis was one with bilateral tuberculosis of the kidneys who no longer had symptoms and whose working capacity was restored. Complete recovery also resulted from 14 months' treatment with a total dose of 3,724 gm. of *p*-aminosalicylic acid intravenously and 1,737 gm. orally in an apparently hopeless case with paralysis of bladder and rectum and paraplegia. At present *p*-aminosalicylic acid administered by intravenous drip and combined with streptomycin is to be considered the method of choice for the treatment of tuberculous meningitis, miliary tuberculosis, and other severe tuberculous conditions.

Intestinal Upset After Treatment with Chloramphenicol.—Of 21 nursing infants between the ages of two and six months with pertussis treated effectively with chloramphenicol (chloromycetin®), seven had intestinal upset within 14 days after the discontinuation of therapy. Reduction of the bacterial flora in the intestines caused by the drug may result in dyspeptic disturbances, with recurrent increase of the bacterial flora after discontinuation of therapy. To 37 nursing infants with pertussis treated with chloramphenicol, 1 tablet of living Lactobacillus acidophilus was given three to five times immediately after administration of chloramphenicol was discontinued, and in addition up to 7% beta lactose was added to the formula. The administration of living lactic acid bacteria and lactose is recommended for prevention of intestinal disturbances after administration of chloramphenicol.

*Report on Case of Intermittent Claudication Treated with Hexamethonium Bromide. C. H. Gurd.—p. 58.

Hexamethonium Bromide in Intermittent Claudication.—The patient described had had several operations on the kidneys. Following the first, bilateral femoral thrombosis developed. On examination the feet were cold and the pulse of the posterior tibial, popliteal, and dorsalis pedis arteries could not be felt. Because of the risk and doubtful benefit of operation a chemical sympathectomy with hexamethonium bromide was done, starting with a small dose with gradual increments until the patient was taking 0.5 gm. three times a day. The feet became less waxy and took on a rosy pink color; no pulsation, however, could be felt. The blood pressure fell about 20 mm. in each arm. The fact that hexamethonium bromide causes vasodilatation in the lower extremity appears to favor it in the treatment of this disease.

Roentgen Appearance of Primary Pleural Cancer.—Primary pleural cancer includes endothelioma, sarcoma, and carcinoma. Of the 12 primary pleural cancers observed in three years by Pfeifer and Weiss, 11 were histologically verified while the patient was alive and in the 12th the growth was morphologically identified at necropsy. The authors employ the following diagnostic procedures: (1) fluoroscopy of the thorax; (2) withdrawal of the pleural exudate by puncture; (3) induction of a diagnostic pneumothorax; (4) a "second" fluoroscopic examination in two planes of exposure; (5) thoracoscopy and biopsy through the thoracoscope from the costal and visceral pleura or, if thoracoscopy proves impossible, exploratory thoracotomy with biopsy from both pleuras. They were able to carry out these procedures without complications in all 11 patients. The roentgenogram is not pathognomonic for primary cancer of the pleura, but the following findings suggest pleural cancer: (1) thickening of visceral and costal pleuras with nodulated or granulated outline, (2) absence of displacement of heart or mediastinum toward the healthy side; in advanced cases the diseased side may show shrinkage; (3) rigidity of the thorax on the diseased side and absence of mediastinal shift during respiration, even after a pneumothorax has been made; (4) tumor nodules the size of a cherry or plum on the thickened pleura; and (5) erosions of the ribs at the level of the pleural thickening.

Etiology of Prolapse of Gastric Mucosa.—Etter discusses the roentgenologic aspects of prolapse of the gastric mucosa into the pylorus and the duodenal bulb and describes a case in which the prolapse was unusually large. It was necessary to perform gastric resection because of increasing pyloric stenosis. Examination of the surgical specimen disclosed lipomatosis of the submucous coat of the antrum, which had resulted in extensive shifting of the mucosa in relation to the muscular coat and thereby produced the mucosal prolapse.

Roentgenologic Signs in Digestive Tract After Vagotomy.—Of 110 patients who had been subjected to vagotomy, 44 were reexamined roentgenologically from 18 to 24 months later. Roentgenoscopy was done first when the stomach was empty, and then again after a contrast medium had been introduced. Severe morphologic and functional changes were demonstrable throughout the digestive tract. Severe hypertrophic gastritis, disturbances in tonus and motility of the small intestine, and dyskinesia of the colon were the most important disturbances observed in patients following vagotomy. The author comments on the nature and possible etiology of these signs on the basis of his own observations and those reported in the literature.

ACTH and Survival of Homografts.—Homografts in man and animals do not survive permanently because the host forms antibodies to the foreign proteins they contain. Since it was found that the use of corticotropin (ACTH) and cortisone alters the antigen-antibody relationships, the authors studied the effect of corticotropin on the survival of homografts in one man, one woman, and one girl with third degree burns of the trunk and thighs. None had had corticotropin or adrenocortical hormone therapy previously, and all had good adrenocortical reserves. When autografts and homografts were implanted, 100 mg. and 50 mg. of corticotropin were given daily to the adult patients and the child, respectively. Autografts and homografts took well, but the former grew and survived, whereas the latter degenerated in the woman after 11 weeks, and in the child after 51 days. In the man, who died, some of the homografts had died before his death. It is believed that, had he lived, the other homografts would not have survived because sections taken from them after death showed a very thin epithelium and absence of well-formed rete pegs. The length of survival of the homografts seemed to be related to the intensity of adrenocortical response. Corticotropin did not prevent bacterial invasion and clinical signs of infection, nor did it increase the percentage take of delayed autografts. High granulations grew over the burned areas. Side-effects attributable to corticotropin were moon face, mental disorientation, glycosuria, and, in the two adults, a diabetic state. Corticotropin prolonged but did not perpetuate the survival of homografts on deep flame burns. Early skin closure is, therefore, as urgent now as it was before the discovery of this hormone.

Estrogenic Hormone Implants in Vaginal Hypoplasia and Aplasia.—Estrogenic hormones were implanted in a 21-year-old married woman with severe vaginal hypoplasia and in a 24-year-old married woman with congenital vaginal aplasia. The first patient was actually a female castrate, her right ovary having been removed when she was three years old because of a cyst, and there was evidence of ovarian deficiency. Eight 25 mg. pellets of estradiol implanted subcutaneously in the thigh brought about improvement that became more pronounced after three 100 mg. pellets of stilbestrol were also implanted subcutaneously in the thigh 11 months later. In a follow-up three years later, sexual intercourse was described as satisfactory, and the husband, who prior to the treatment had considered seeking an annulment of the marriage, regarded their relationship as normal. The second patient, who presumably had no ovarian tissue, was almost certainly a male pseudohermaphrodite. Three 100 mg. pellets of estradiol, and six months later six 50 mg. pellets of estradiol were implanted subcutaneously in the thigh of the patient. The improvement was pronounced, and during a follow-up nine months later she reported that sexual relations were being accomplished with ease. It appears that implants of estrogenic hormones may be valuable therapy for patients with congenital vaginal aplasia, since many of them are deficient in ovarian function. Moreover, with this treatment, hospitalization, surgical intervention, and application of instruments to the genitalia are avoided.

Hypertension and Tuberculosis of Adrenals.—Left adrenalectomy combined with bilateral subdiaphragmatic sympathectomy was performed on a 37-year-old woman with essential hypertension. The blood pressure was restored to normal. The patient resumed her work and was in good health eight months after the surgical intervention. Microscopic examination of the removed adrenal gland revealed pronounced hyperplasia of the adrenal medulla associated with disseminated caseous nodular tubercles. These findings suggested that the patients' hypertension was conditioned by the medullary hyperplasia, which resulted from the tuberculous infection. While tuberculosis commonly produces hypocorticalism, it is rather exceptional for it to result in hypertension, demonstrating that there may be other manifestations of tuberculosis of the adrenal gland than Addison's disease.

Common Bile Duct Compression Due to Chronic Pancreatitis.—In the course of 1,575 surgical interventions on the biliary tract performed under radiomanometric control during a 10 year period 36 cases of common bile duct compression due to chronic pancreatitis were observed. The latter condition was manifested by inflammatory swelling and induration of the head of the pancreas. In 2 of the 36 cases roentgenograms and manometric readings revealed complete stenosis of the common bile duct; recovery followed choledochoduodenostomy. In 18 cases a relative stenosis of the common bile duct was demonstrated by abnormally high manometric readings and by the roentgenographic appearance of the common bile duct, which revealed a disturbance of evacuation and deformity of the portion of the common bile duct close to the pancreatic tissue, with dilatation of the upper two-thirds of this portion. A syndrome consisting of pain, chills, elevation of temperature, and icterus was observed in 12 of the 18 cases, while pain alone occurred in 6 cases. Narrowing of the common bile duct was revealed roentgenographically in the remaining 16 cases, but the manometric readings were normal; symptoms were limited to the common bile duct in 6 of these cases, and the gallbladder was involved in 10 cases. The authors emphasize that diagnosis of these various conditions may be established only by radiomanometric control during surgical intervention. Deformity of the common bile duct due to chronic pancreatitis differs considerably from that due to compression by a pancreatic cancer or to stenosis due to a tumor of the ampulla of Vater. Recovery resulted from external drainage of the biliary tract in four of seven cases in which it was performed; the three other cases were therapeutic failures. Recovery resulted from internal drainage of the biliary tract in all the 21 cases in which it was carried out. Consequently systematic internal drainage of the biliary tract is recommended by the authors. Cholecystogastrostomy is feasible only in the absence of lesions due to cholecystitis. With this exception, preference should be given to choledochoduodenostomy following cholecystectomy in cases of complete or relative stenosis, while cysticoduodenostomy is to be considered the method of choice in cases with roentgenographic evidence of stenosis of the common bile duct but normal pressure readings. This intervention is simple and harmless, and excellent results were obtained in 16 cases in which it was performed.

Enuresis.—The incidence of enuresis is considerably higher among children who have had early and rigid toilet training than among those allowed to achieve control naturally (34 of 38 as compared with 2 of 35). Severity and coercion may succeed in establishing a habit of continence, but subsequent anxiety and frustration may cause regression. Restoration or creation of a favorable psychological environment free from anxiety and with opportunities for normal development may reverse the process and reestablish control. Enuresis was noted in only two of 35 children who were subjected to severe frustration but who had not had coercive toilet training. Frustration alone, therefore, does not produce enuresis; it merely initiates it.

Vitamin E in Collagen Diseases.—The mode of action of vitamin E in correcting the metabolism of the connective tissue in patients with collagen diseases is not known. The hypothesis was advanced that this vitamin and its derivatives may inhibit hyaluronidase, which is considered to be responsible for the pathological picture of these diseases. The author studied the in vivo and in vitro influence of vitamin E and tocopherols on testicular hyaluronidase. A wheal was produced in the left forearm of 15 fasting patients at complete physical rest by injecting 0.1 cc. of hyaluronidase along with 0.1 cc. of a hemoglobin solution as a dye that does not affect the enzyme. After the spreading reactions were measured, 1 gm. of water-soluble vitamin E was given (500 mg. intravenously and 500 mg. intramuscularly), and a new wheal was produced in the same forearm with the same procedure. The new spreading reactions were definitely less extensive than the first. Simultaneously 0.1 cc. of an isotonic sodium chloride solution along with 0.1 cc. of hemoglobin solution were injected in the right forearm of the same patients. These spreading areas before and after administration of vitamin E were the same. In a second study 0.1 cc. of an aqueous solution of α-tocopherol and 0.1 cc. of hyaluronidase with 0.1 cc. of hemoglobin solution were injected in the left forearm of 15 other patients, while an equal dose of an aqueous solution of α-tocopherol was injected in the right forearm of the same patients along with 0.1 cc. of an isotonic sodium chloride solution and 0.1 cc. of hemoglobin solution. The spreading reactions of the left forearm were smaller than those of the right forearm. Additional in vitro studies demonstrated that this vitamin and its derivatives inhibit the mucinolytic enzyme even in very low concentrations, and increase the antihyaluronidase activity of human serum. Thus, one important function of vitamin E and its derivatives may be to serve as regulators of hyaluronidase activity in man. When the vitamin E levels drop below a critical concentration in the body, then the enzyme may attack its substrate. The author, in agreement with Steinberg, concludes that collagen diseases are caused by a deficiency of α-tocopherol. This may result from (*a*) insufficient intake of vitamin E, (*b*) abnormal intestinal absorption of this vitamin as seen in cases of cirrhosis of the liver, and (*c*) normal intake and absorption but abnormal use of tocopherols by the connective tissue. If this hypothesis is accepted, the good results obtained by some authors with vitamin E in patients with collagen diseases are easily understood.

Visammin in Angina Pectoris.—Visammin (khellin) was given orally to 20 patients with angina pectoris in daily doses of from 60 to 100 mg. for 3 to 12 days. All the patients were benefited, and in some the anginal attacks disappeared during the therapy. Mild nausea was the only side-effect. The electrocardiograms of some patients with mild coronary disturbances who had improved returned to normal and remained normal for six days after the therapy was interrupted, revealing a prolonged pharmacological effect of the drug. In other patients with coronary disturbances in whom anginal pain was alleviated by the drug the electrocardiograms changed only slightly. In patients with left ventricular preponderance in whom anginal attacks had become less frequent and surprising improvement had occurred, the electrocardiograms remained unchanged. The drug had a vasodilating action on the coronary system but did not influence the blood pressure of the patients.

*Reduction of Surgical Blood Loss by Hexamethonium and by Postural Control. T. Hoffmann.—p. 711.

Reduction of Blood Loss During Surgical Intervention.—The C_6 and C_5 derivatives of the methonium salts (hexamethonium and pentamethonium) block the autonomic ganglions. By increasing the stimulus threshold for acetylcholine, they exert the same effect on the nerve cells as curare does on the muscles. General vasodilatation of the arterioles results in lowering of the blood pressure of various degree, depending on the individual, his posture, and the functional condition of the ganglions. Lowering of the blood pressure combined with positioning of the patient on an inclined plane with the operative area at the highest point reduces the loss of blood during surgical intervention. With systolic values of 40 to 60 mm. Hg the loss of blood may be reduced to a minimum. Consequently the amount of blood required for replacement is insignificant. It is, however, imperative that the total circulating amount of blood be maintained by immediate replacement of even the smallest loss of blood, and hyperoxygenation of the blood must be assured. The angle of the plane determines to a considerable extent the level of the blood pressure, and this makes possible controlled lowering of blood pressure. It should be emphasized that only in the hands of an experienced anesthetist is this method without risk.

*Id.: IV. Summarizing Viewpoints. C. Crafoord.—p. 394.
Hyperactive Carotid Sinus. L. Lindén.—p. 400.

Surgical Treatment of Heart Diseases in Children.—Mannheimer reviews the clinical diagnosis and indications for operative treatment of congenital heart disease in children, and urges that all patients with congenital heart defects be admitted to special cardiological departments for examination. He considers briefly congenital heart defects that do not produce cyanosis, such as patent Botallo's duct, coarctation of aorta, anomalies of aorta and subclavian artery, and pulmonary stenosis without an overriding aorta and without septal defects. He discusses the defects that cause cyanosis, such as the tetralogy of Fallot, pulmonary atresia with overriding aorta and defect of the interventricular septum, tricuspid atresia, and Fallot's triad. Valvulotomy by Brock's method done by Crafoord in 10 cases of pulmonary stenosis with septal defect resulted in improvement in eight cases; two patients died following the intervention. Follow-up examination of 78 cyanotic children, 76 with the tetralogy of Fallot and two with tricuspid atresia, operated on in Stockholm from late 1947 to early 1950, mainly at the age of from 2 to 10, showed 10 deaths. The mortality, however, has been decreasing steadily, and the results of the anastomosis operation in suitable cases of congenital cyanosis are considered encouraging.

Surgical Treatment of Coarctation of Aorta.—Coarctation of the aorta is often discovered accidentally. Jönsson and Karnell find that the only rational treatment consists of resection of the stenosis and suture of the aorta. Of 120 patients with coarctation of the aorta examined, 94 were operated on. There were seven deaths, but one was not attributable to the intervention. All the survivors were improved subjectively. Improvement occurs more slowly in older patients. Of the objectively demonstrable improvements, normalization of the blood pressure in arms and legs is the best sign that the anastomosis is functioning satisfactorily. Not all cases are operable. If the distal end of the aortic arch is long and wide, the condition is favorable from both the operative and prognostic viewpoint; if it is long and narrow, the prognosis is less favorable; if it is short, operation is often more difficult; and if the distal end is absent, operation is impossible. The changes in the aorta that make suturing less successful increase so much between the ages of 25 and 30 that patients over 30 are not good risks. An ideal age for operation is thought to be about 10 years. The presence of another heart defect does not in principle constitute a contraindication, and it may at times increase the indication, as when there is a patent arterial duct. If the diagnosis of coarctation of aorta is established, which can be done by simple clinical methods, and the patient is of operable age, operation should not be delayed because of the absence of subjective symptoms. Careful clinical and functional analysis, however, is necessary before operation.

Surgical Treatment of Mitral Stenosis.—The indications and contraindications for mitral commissurotomy are discussed from the standpoint of heart catheterization studies. The patients who have survived operative treatment of mitral stenosis have usually shown subjective improvement. How long the improvement will continue is not yet known; Bailey's first patients, operated on more than two years ago, are still free of symptoms. Of 19 patients with mitral stenosis operated on by Crafoord, 3 died immediately following operation, all from embolism. Moderate mitral insufficiency developed in two patients. Werkö concludes that in the majority of cases isolated mitral stenosis can be treated operatively with good results. Operation is not indicated in patients with slight narrowing of the ostium reflected in relatively insignificant symptoms. In cases of marked mitral stenosis it is important to operate early. Operation should not be done when the disability depends mainly on pulmonary changes, changes after arterial embolism, or cardiac insufficiency. The immediate operative mortality is low in young patients with uncomplicated valves, but increases with the age and with increasing involvement of the heart and circulatory system.

Summary of Surgical Treatment of Diseases of Heart.—Crafoord stresses the importance of teamwork in diagnosis and treatment of cardiovascular defects and diseases. He stresses the significance of angiocardiography and heart catheterization. When correctly carried out almost no risk is associated with these examinations. In over 1,000 angiocardiographic examinations carried out in Sweden only two deaths occurred, both in cyanotic newborn infants. Angiocardiography provides such exact information preoperatively that the surgical plan can be formulated on this basis. Heart catheterization is indispensable in the evaluation of mitral stenosis, isolated pulmonary stenosis, and cardiac defects that cause cyanosis. A smaller number of atypical, prog-

BOOK REVIEWS

Cardiac Emergencies and Heart Failure: Prevention and Treatment. By Arthur M. Master, M.D., Cardiologist, Mount Sinai Hospital, New York, Marvin Moser, M.D., 1st Lt., USAF (MC), Walter Reed Army Hospital, Washington, D. C., and Harry L. Jaffe, M.D., Adjunct Physician, Cardiology, Mount Sinai Hospital, New York. Cloth. $3. Pp. 159, with 13 illustrations. Lea & Febiger, 600 S. Washington Sq., Philadelphia 6, 1952.

The sudden development of a condition that requires prompt and intelligent treatment is a common occurrence in cardiac disorders. Ready access to information on how to treat a patient at that time is very important to the practicing physician. He wants precise directions for handling the emergency and not a learned treatise on the mechanisms involved. In this small book, Dr. Master and his group, out of their long experience in the treatment of cardiac patients at Mount Sinai Hospital in New York and in private practice, have provided for the general practitioner just what he needs to know in the management of the cardiac emergencies. In spite of the small size of this book, a broad field of therapy is covered. In the nine chapters, the following subjects are considered: arrhythmias, acute heart failure, coronary artery insufficiency, coronary artery thrombosis, syncope, hypertensive crises, surgical emergencies, and traumatic heart diseases. A few well-chosen illustrations and tables supplement the text. Although this book is simply written and concise, it is still up-to-date, including a discussion of the important new remedies, such as procaine amide hydrochloride in the treatment of arrhythmias and mercaptomerin (thiomerin®) sodium in the treatment of congestive heart failure. The practicing physician will welcome this practical little reference book on the treatment of cardiac emergencies.

The Human Blood Groups Utilized in Disputed Paternity Cases and Criminal Proceedings. *By P. H. Andresen,* Chief, Municipal Blood Bank, Bispebjerg Hospital, Copenhagen. Cloth. $3.75. Pp. 114. Charles C Thomas, Publisher, 301-327 E. Lawrence Ave., Springfield, Ill.; Blackwell Scientific Publications, Ltd., 49 Broad St., Oxford, England; Ryerson Press, 299 Queen St., W., Toronto, 2B, 1952.

The objective of this book dealing with the human blood groups is, according to Andresen, to discuss the practical application and medicolegal significance of the subject. This material as is presented does not require too much knowledge of biology, and thus the information should be understood quite readily by physicians, lawyers, and trained technical personnel. The reader is introduced to a review of the Landsteiner system of blood grouping, the various subgroups, the M-N system, and the Rh system.

The author discusses the medicolegal utilization of blood groups in disputed paternity cases. It is pointed out that blood group determinations must be performed by specialists possessing wide training in the scientific and practical bases of blood group determinations and who are also thoroughly familiar with forensic medicine and the ordinary problems connected with the use of biologic tests for judicial purposes. Of the three essential rules governing the interpretation of disputed paternity cases, Andresen points out that although the newborn infant's blood group is not fully developed, renewed examination somewhat later is required only in exceptional cases. As a rule, a baby should be 1 month of age before the blood group is determined. This note by Andresen is exceedingly important: "In Denmark, all medico-legal laboratory tests are performed at the University Institute of Legal Medicine in Copenhagen—with the exception of the actual toxicological analyses, which are done at the University Institute of Pharmacology. This means that all tests are performed in an institution, economically as well as administratively, independent of law courts and police." We in this country can profit tremendously in this regard.

This book is highly recommended to all who are interested in the subject of human blood groups.

Doctors in Blue: The Medical History of the Union Army in the Civil War. By George Worthington Adams. Cloth. $4. Pp. 253, with illustrations. Henry Schuman, Inc., Publishers, 20 E. 70th St., New York 21, 1952.

In the first few chapters of this book is a sad story of mismanagement at the start of the Civil War brought about by the lack of an effective system of finding the wounded on the battlefield and of a hospital system whereby they could be properly cared for. The military personnel for the north that gathered in the wounded at first were simply volunteers from various units of the army, almost wholly untrained in medical work. Many of the physicians at this time were volunteers from civil life who came and went more or less at their own convenience. Civilian teamsters, hired to drive ambulances, ran away or broke into the liquor supplies and behaved abominably, refusing to give water to the wounded, refusing to put the wounded in ambulances, and in some cases even going through the pockets of their helpless passengers. From this "frightful state of disorder" Surgeon General William A. Hammond concluded that the army had to have an ambulance corps controlled by the medical department rather than by the Quartermaster Corps. It was nearly four years, however, before this was brought about, largely through the strenuous effort of civilian reformers led by Dr. Henry I. Bowditch of Boston whose wounded son was brought off the battlefield on a horse; when at last an ambulance reached him, it was without water and its driver would procure none. When young Bowditch died of his injury, his father "went into battle" against the War Department's apathy, and he never ceased fighting until the Ambulance Corps Act of 1864 was on the statute books. Previously, however, Jonathan Letterman, a regular army medical officer, had tried to improve the situation by organizing the supply system on the divisional basis and by organizing an ambulance and field corps for the Army of the Potomac. He set up a system of divisional hospitals and provided for division of labor among the medical officers attached to each hospital. The ambulance details now were trained daily. Letterman set up tent hospitals organized by divisions but grouped together to make a corps hospital with one medical officer in command of all. The Letterman ambulance system reached its peak of development on Aug. 24, 1863, with the issuance of a general order that made the Army corps the normal ambulance unit and laid down details for management of the ambulances. Letterman's ambulance service for the Army of the Potomac became a model for other armies; in fact, it was the basis of the ambulance service of most of the armies of the world until World War I. J. Marion Sims, an American surgeon, was decorated by France for having introduced it into the French Army during the War of 1870. A typical Letterman division hospital train consisted of 14 army wagons and 4 medical wagons loaded with 22 hospital tents and medical supplies and equipment considered sufficient for the care of more than 7,000 men in a division. Thus, the mismanagement of the wounded in the early battles of the war evolved from confusion to an orderly system.

Having in mind our present advancements in surgical technique and new drugs effective against infection, the medical treatment of so many sick and wounded men during our Civil War now seems crude. Chloroform was the chief anesthetic. Throughout the four years some 80,000 general anesthetics are said to have been given with 37 deaths resulting from the chloroform, 4 from ether, and 2 from a mixture of the two anesthetics. It is interesting to learn that maggot therapy was rediscovered in the Civil War, only to be forgotten, then rediscovered in World War I, and now almost forgotten again. The one great orthopedic contribution to the Civil War was the splint, invented by Surgeon John T. Hodgen of St. Louis, a device that is still in use, providing extension and preventing contraction of the limb and giving comfort to the patient. Pyemia, tetanus, "surgical fevers," erysipelas, typhoid, dysentery, malaria, and gangrene were serious problems. Tetanus flared up alarmingly in the field hospital at the battle of Antietam, no doubt largely because the hospital was an old stable, the floor of which had

---

The reviews here published have been prepared by competent authorities and do not represent the opinions of any official bodies unless specifically stated.

been 2 ft. deep in manure. Many of the wounded at the Battle of the Wilderness were bedded on the floors of Fredericksburg stables. Tetanus, however, was relatively rare, the number of cases being given as 505 with a mortality of 89%. With all their flaws, the Civil War hospitals, the author says, may be considered a credit to a nation, which in four years had created a vast system of 136,000 beds.

The medical record of the Civil War, on the whole, the author says, was good. This has not been generally realized, partly because the war took place before bacteriology and aseptic surgery made some of the war's medical accomplishments seem "piddling" or "irrelevant." The Civil War's morbidity and mortality rates are said to have been 2,435 and 53.4 per thousand respectively.

The author did much research before writing this book, and many of his sources of information comprise an appendix at the close of his book. It seems that he well deserved the degree for which this material was first presented as a doctoral dissertation in history at Harvard University.

Psychotherapy of Psychosis. By Gustav Bychowski, M.D., Assistant Clinical Professor of Psychiatry, New York University College of Medicine, New York. Cloth. $5.75. Pp. 328. Grune & Stratton, Inc., 381 Fourth Ave., New York 16, 1952.

The author devotes nearly all of his 34 chapters, ranging in topic from the personality of the psychiatrist to problems and prospectives, to a review of current psychoanalytic theories and techniques in the therapy of the so-called functional psychoses. He bows to other schools of thought only occasionally, e. g., in an obscure section in the phenomenology of Husserl, Minkowski, and Kronfield and in occasional passages in which Bleuler, Schneider, and Goldstein are quoted to the effect that schizophrenia may, after all, be a constitutional, metabolic, or neurophysiological disorder. Bychowski also admits *pari passu* that hypnotism "with strong suggestion," pharmaconarcosis, and even insulin therapy might be helpful as ancillary techniques of treatment, but gives no specific directions as to how to employ these in clinical practice. Instead, the author attempts to combine an outmoded Kraepelinian nosology with a welter of Freudian metapsychology expressed in the usual jargon of "id," "narcissistic identification," "weak ego core," "counter-cachexis," "primordial introjection," and similar terms vaguely meaningful to the tolerant lexicographer of psychoanalysis but for the most part mercifully beyond the ken of the general practitioners.

A few quotations from only 10 pages of the book will suffice to illustrate its style and content. Page 14: "A patient, seemingly possessed of complete indifference, could produce a strong emotional reaction either temporary or of long duration"; page 16 ff.: "The schizophrenic is affected in his vital dynamics and is thus deprived of the organization necessary to assimilate dynamics"; page 19: "The morbid emotion depersonalizes the ego and shifts the accent to the other person in whose place one would rather like to be"; page 20: "After all, no matter what theory one holds regarding the initial and the essential disturbances in schizophrenia, still nobody could deny that schizophrenics think, speak, perceive and write with their brains like anybody else"; page 23: "By way of analysis of the stream of thought I could show that the waves of energy originating in the brain of schizophrenics have special characteristics. They are incomplete and imperfect as regards their tempo as well as the degree of their delimitation. The waves, while not directed by some superior impulse, become easily independent and are unable to reach their goal. The inhibition of the stream of cerebral energy . . ."

And so on to page 245: "The impact of the sadistic superego which time and again hits the ego and punishes it with suffering and misery seems to form the main dynamic in cases of chronic depression"; page 315: "Undoubtedly many of the so-called psychopaths are latent schizophrenics where the peculiar acting out occurs as a manifestation of split-off parts of the ego."

To nearly all nonpsychiatrists (and most modern psychiatrists and psychoanalysts) such statements will sound like conceptual mystifications and semantic confusions. Conceivably, however, to some analysts still immersed in classical animistic metapsychology they may represent nuggets of insight and erudition. Bychowsky's book is recommended only to the latter.

Contemporary Correction. Editor: Paul W. Tappan, Professor of Sociology and Lecturer in Law, New York University, New York. Cloth. $5.50. Pp. 434, with 20 illustrations. McGraw-Hill Book Company, Inc., 330 W. 42d St., New York 18; Aldwych House, Aldwych, London, W.C.2, 1951.

This book presents a comprehensive symposium on the major developments and trends in the field of correction. In the foreword Sanford Bates, commissioner of the Department of Institutions and Agencies of the state of New Jersey, says, "Our penal system cannot yet be held as a success. It is the hope of Dr. Paul Tappan and the rest of us that this volume may do something toward encouraging and stimulating more widespread and persistent effort to make it so." With this purpose in mind the editor has obtained articles by qualified leaders in their respective fields and has grouped them under five main headings: part 1, Correction: Preliminary Consideration; part 2, Administrative Organization and Classification; part 3, Programs in the Correctional Institution; part 4, Types of Correctional Institutions; part 5, Extramural Treatment. To one unfamiliar with this field the book will provide an amazing experience in the revelation of the myriad problems involved in prison life. To others it will be a welcome source of information.

Physicians will be particularly interested in two chapters under part 3; in chapter 12, on medical services, correctional medical services are discussed from the viewpoint of what medical services must be rendered an inmate during his institutional residence and what the rehabilitative effects of such services will be after the inmate's release. Both the short range and long range aspects of this program are discussed in considerable detail by Dr. Justin K. Fuller, medical consultant of the Department of Corrections of the state of California and former director of the Federal Bureau of Prisons. He states, "The situations and problems that confront a correctional medical service not only are as numerous, varied, and difficult as are those found in any public or private hospital, but present some peculiar features not common to other types of medical service. . . . Acceptable modern standards of medical service include not only the diagnosis and treatment of physical illness but also psychobiology, in its broadest sense, and research. These functions must be recognized and provided for in the correctional field because of the influence that a proper medical service may have on reducing the incidence of conduct disorder, delinquency, and crime." Chapter 14, on group therapy, further elaborates on one phase of the medical program and discusses means and methods of approach. This chapter is written by Lloyd McCorkle, director of the Highfield Project in New Jersey, formerly a group psychotherapist at the Fort Knox Rehabilitation Center for military prisoners, and a prison administrator with the U. S. Army of Occupation, Japan. His discussion contains many practical suggestions together with examples of technique used.

Understanding Heredity: An Introduction to Genetics. By Richard B. Goldschmidt. Cloth. $3.75. Pp. 228, with 49 illustrations. John Wiley & Sons, Inc., 440 Fourth Ave., New York 16; Chapman & Hall, Ltd., 37-39 Essex St., Strand, London, W.C.2, 1952.

Heredity, or the science of genetics, has developed so rapidly and so precisely within the last 50 years that it has become the most central and respected of all the biologic sciences. Furthermore, it embraces topics that are of vital concern and interest to everyone. In this small book one of the world's foremost geneticists has opened the door for everyone to this most recently developed science. The author discusses in simple but exact terms such topics as the machinery of heredity, the mode of inheritance of plant and animal characters, including some human, and the origin of new variations by mutation. Helpful illustrations and charts appear. In the concluding chapter the author gives a glimpse of the more technical facts and problems of genetics. He introduces the reader to the topics of how mutations are studied, how genes act physiologically, and how genetics contributes to an understanding of evolution. The book is not a textbook and not a reference book for the specialist. It is what its title indicates, an introduction to the exciting principles and problems of genetics for the person with little or no previous knowledge of this most fascinating and important biologic subject. The book is authoritatively and well written.

Liver Injury: Transactions of the Tenth Conference, May 21-22, 1951, New York, N. Y. Edited by F. W. Hoffbauer, M.D. Cloth. $3.75. Pp. 320, with 42 illustrations. Josiah Macy, Jr. Foundation, 565 Park Ave., New York, 1951.

This book is a verbatim report of a two day conference attended by some 25 of the leading investigators in the field of liver disease. As in all Macy Foundation conferences the discussion is centered around five or six informal papers. In this volume the following subjects are presented: serum proteins and lipids by Roy H. Turner; mechanism of action of lipotropic factors in animals by Camillo Artom and action of lipotropic factors in man by David Cayer; experimental ischemia of the liver and hepatic coma by A. M. Rappaport; microanatomy of the hepatic vascular system by B. G. Maegraith and the effect of insulin on the liver in normal and diabetic men by Sheila Sherlock, A. G. Bearn, and B. Billing; and liver disease in Jamaican children by Kenneth R. Hill. Much of the material presented represents work in progress and is unpublished. The discussion is highly informal and because of the character of the participants highly informative. This volume is particularly well illustrated with tables, graphs, and plates. It has been well edited so that it reads easily. Pertinent references are included.

This is an extremely interesting and stimulating volume, which should be read by all those interested in the field of liver disease. Although much of the material is hypothetical and is only of theoretical interest at present, it should prove of interest to anyone with an inquiring mind.

Die Bluteiweisskörper des Menschen: Untersuchungsmethoden und deren klinisch-praktische Bedeutung. Von Prof. Dr. med. Ferdinand Wuhrmann, medizinischer Chefarzt, Kantonsspital Winterthur, Zürich, und Dr. Ing. Chem. Charlie Wunderly, wissenschaftlicher Oberassistent der medizinischen Universitätsklinik Zürich. Second edition. Cloth. 43.70 Swiss francs. Pp. 387, with 145 illustrations. Benno Schwabe & Co., Klosterberg 27, Basel 10, 1952.

The second edition of this excellent compilation gives, as does the first edition, detailed data on the chemistry of the plasma proteins, qualitative and quantitative protein reactions, physical, chemical, and clinical methods of study as well as the clinical significance of the plasma proteins in different disease conditions, and the production of blood proteins. Newer material, which is extensive, includes the methods and data obtained from paper chromatography, electrophoresis, spectrophotometry, ultracentrifugation, and the measurement of combination and dissociation phenomena. The material is presented in textbook fashion, and the techniques of different methods and tests are given in detail. The statements are well documented, and the extremely free use of bibliographic references, especially the European ones, is valuable for anyone wishing to make additional studies of the material. Of value to the clinician is the section (76 pages) on blood plasma data in different disease conditions and the chapter on fibrin, globulin, and albumin variations in myeloma, leukemia, anemia, kidney, liver, gastrointestinal and skin diseases, as well as in shock and other conditions. The book should be very helpful and time saving for anyone having problems or inquiries about blood proteins.

Rheumatic Diseases Based on the Proceedings of the Seventh International Congress on Rheumatic Diseases. Prepared by Committee on Publications of American Rheumatism Association, Charles H. Slocumb, M.D., Chairman. Cloth. $12. Pp. 449, with 126 illustrations. W. B. Saunders Company, 218 W. Washington Sq., Philadelphia 5; 7 Grape St., Shaftesbury Ave., London, W.C.2, 1952.

This volume is prepared from the talks or abstracts of the talks that were presented at the Congress on Rheumatic Diseases held in May and June, 1949. The subject matter includes such topics as histology and biochemistry of connective tissue, hormone therapy, physical rehabilitation, orthopedic surgery, psychogenic rheumatism, experimentally induced lesions, and serologic studies. The papers have been grouped into chapters according to topic discussed.

The current thinking and practice of leaders from all over the world in clinical and laboratory research are presented. Although this material was originally presented in 1949, much of it is still pertinent and of current interest. This volume will be of value to those interested in rheumatology and will serve as a milepost along the difficult road of progress in the better understanding of rheumatic disorders.

When Doctors are Patients. Edited by Max Pinner, M.D., and Benjamin F. Miller, M.D. Cloth. $3.95. Pp. 364. W. W. Norton & Company, Inc., 101 Fifth Ave., New York 3, 1952.

This book was written by physicians who are or were patients suffering from serious chronic illnesses. Some of them write under their real names and others under pseudonyms. Some of their subjective descriptions of the diseases that attacked them are short, others are quite detailed. All of them are particularly interesting because the writers are both physicians and patients. Many of the accounts are beautifully written. They reflect a stoic attitude toward life, which persons in good health too infrequently attain. These seriously ill physicians are still carrying on the practice of medicine either from a desire to keep busy or from a sense of responsibility to their families. Some of the diseases from which they suffer are multiple sclerosis, epilepsy, hypertension, migraine, manic depressive psychosis, rheumatoid arthritis, pulmonary tuberculosis, cancer, morphine and alcohol addiction, coronary occlusion, sinusitis, an acute anxiety state, and chronic brucellosis. The reader will not only learn much from these unusually instructive case histories, but he will be inspired and made thankful that he is able to live without the burden of disabling chronic disease.

Clark's Applied Pharmacology. Revised by Andrew Wilson, M.D., Ph.D., F.R.F.P.S., and H. O. Schild, M.D., Ph.D., D.Sc., Eighth edition. Cloth. $7. Pp. 691, with 120 illustrations. Blakiston Company (division of Doubleday & Company, Inc.), 1012 Walnut St., Philadelphia 5, 1952.

In undertaking revision of this well-known text, Drs. Wilson and Schild have adhered to Professor Clark's original pattern of discussing scientific evidence for the therapeutic action of the more important drugs and emphasizing the importance of this knowledge in the clinical application of the drugs. The text has been considerably revised, so that the advances of the 12 years intervening between editions could be incorporated without appreciably lengthening the book. Each chapter concludes with a short bibliography and a selection of drugs both from official British and American publications and from "New and Nonofficial Remedies." Dosages throughout the text are expressed in the metric system. The book can be recommended to medical students and practitioners as a convenient-sized volume that discusses the essentials of pharmacology in a clear, understandable manner.

Advances in Enzymology and Related Subjects of Biochemistry. Volume XII. Edited by F. F. Nord. Cloth. $9.75. Pp. 570, with illustrations. Interscience Publishers, Inc., 250 Fifth Ave., New York 1; 2a Southampton Row, London, W.C.1, 1951.

This book follows the style of the previous volumes of the series. Various authorities discuss and evaluate the advances that have been made in special branches of enzymology or in some closely allied field in which the author has been active. The nine chapters in this volume include a status report on starch chemistry and the enzymes involved in starch degradation and synthesis, the hydrolysis and synthesis of acetylcholine, oxidation reduction in chloroplasts, carbon dioxide fixation by autotrophs and heterotrophes, enzyme substrate compounds, peptidase specificity, biological methylation by molds, and the reaction of borates with substances of biological interest. Each chapter contains appropriate references, and the volume contains an author and subject index. A cumulative index is also included, which lists the authors and subjects of this and the previous volumes.

Seudoartrosis. Por el Prof. M. Bastos Ansart. Cloth. Pp. 207, with 80 illustrations. Publicaciones médicas José Janés, editor, Muntaner 316, Barcelona, 1951.

This monograph, which is not a reference work, discusses the author's personal experiences with ununited fractures. There is a general discussion of etiology and pathology, followed by a consideration of clinical features. The remainder of the text is devoted to a consideration of therapy. This section covers in some detail the various operative procedures preferred by the author, and he demonstrates some good results. Other existing operative procedures of value described in texts and dissertations on the subject are mentioned only briefly or not at all. The illustrations are pertinent and of fairly good quality, and the index seems to be well detailed. There is no bibliography.

Klinische Elektrokardiographie. Von Professor Dr. Carl Korth, Direktor der medizinischen Poliklinik der Universität Erlangen. Mit einer Einführung in die Grundlagen der Elektrokardiographie und der elektrokardiographischen Technik, von Dr. Joachim Ritzmann. Fifth edition. Cloth. 25 marks. Pp. 302, with 181 illustrations. Urban & Schwarzenberg, Thierschstrasse 11, Munich 22; Meinekestr. 13, Berlin W. 15, 1952.

The fifth revised edition of this textbook of electrocardiography is a valuable addition to other recent German publications on the subject. As in previous editions a clear and concisely written text together with well-selected and well-reproduced illustrations reflects the author's great experience as a clinical electrocardiographer and teacher. Multiple chest leads and aV limb leads are widely applied, and the most important chapters are further clarified by excellent diagrams, some of which are modified or taken directly from various American texts. Only a few inconsistencies in labelling and legends need correction.

Abnormalities of contour are approached from an empirical point of view with great stress upon the type of development and of regression of changes. Vectorial analysis of the abnormal electrocardiogram, recently so much favored, is more or less omitted. Some subjects, like electrolyte imbalance, apart from changes of the calcium level, and acute cor pulmonale, would warrant more emphasis and some illustration. The chapter on cardiac irregularities is excellent, as can be expected from an author who is an "old hand" in the interpretation of complicated arrhythmias. Theoretical aspects, such as the genesis of the normal electrocardiogram, are dealt with relatively briefly, in contrast to the considerable space devoted to technical details and description of instruments. The author's view that "the string galvanometer is today only of historical interest" sounds surprising, especially since he does not hesitate to apply extensively the recent advances achieved in American centers with this type of machine.

As a whole, the book can be recommended primarily as an instructive introduction to clinical electrocardiography.

Physical Rehabilitation for Daily Living. By Edith Buchwald, M.A., A.R.P.T., Director of Rehabilitation Courses for Physical Therapists, Institute of Physical Medicine and Rehabilitation, New York University—Bellevue Medical Center. In collaboration with Howard A. Rusk, M.D., Professor and Chairman, Department of Physical Medicine and Rehabilitation, George G. Deaver, M.D., Professor of Clinical Physical Medicine and Rehabilitation, and Donald A. Covalt, M.D., Associate Professor, Physical Medicine and Rehabilitation. Cloth. $7.50. Pp. 183, with 71 illustrations. McGraw-Hill Book Company, Inc., 330 W. 42d St., New York 18; Aldwych House, Aldwych, London, W.C.2, 1952.

The purpose of this book is to present a program of basic exercise and activity for daily living that can be taught to patients with disabilities of the lower extremities. Its senior author, Edith Buchwald is a registered physical therapist and the director of rehabilitation courses for physical therapists at the Institute of Physical Medicine and Rehabilitation, New York University—Bellevue Medical Center. Her collaborators were Drs. Howard A. Rusk, George G. Deaver, and Donald A. Covalt of the same institute. The members of this team have jointly produced an illustrated manual that serves as a guide in the teaching of an "A. D. L. program" (Activities of Daily Living).

The manual contains seven chapters and is well illustrated. In chapter 1 it is pointed out that the goal of the program is functional training, which involves the physical rehabilitation of the patient in order to enable him to handle himself as sufficiently and as independently as possible. To this end, chapters are included on bed and mat exercises, wheel chair exercises, self-care, ambulation, elevation and travel on crutches, use of wheel chairs and braces, activity of daily living testing, and special equipment and furniture useful in the "A. D. L. program." This book should serve as a useful guide to any member of the rehabilitation team engaged in teaching these activities of daily living to patients.

Recreation Through Music. By Charles Leonhard, Ed.D., Associate Professor of Music, University of Illinois, Urbana. Cloth. $3. Pp. 160, with 29 illustrations. A. S. Barnes & Company, 232 Madison Ave., New York 16, 1952.

This book is of principal interest to educators and recreation directors. As its title indicates, it deals with recreation through music. The roles of making music and listening to music are discussed. The use of music by recreation leaders, the techniques for community singing and choral singing together with procedures for a sing, repertory for a song leader, instrumental classes, instrumental ensembles, and an extensive list of references and song selections are included. For the physician this book might be of special interest in relation to the use of music in occupational therapy. The book itself does not deal with this subject specifically, but a physician with occupational therapy in mind would find little difficulty in translating the materials in this volume into terms of his own needs.

Orthopaedic Appliances Atlas: A Consideration of Aids Employed in the Practice of Orthopaedic Surgery. Volume I: Braces, Splints, Shoe Alterations. Published under auspices of American Academy of Orthopaedic Surgeons, Inc., in cooperation with Office of Surgeon General, U. S. A., and Veterans Administration Department of Medicine and Surgery. Cloth. $10. Pp. 588, with 945 illustrations. J. W. Edwards, 1745 S. State St., Ann Arbor, Mich., 1952.

The purpose of this amazing atlas is to present the development of standards and technical material relative to the construction, prescription, and fitting of orthopedic appliances. It is divided into seven major parts. The first part presents a fascinating historical review. Part two, entitled "Materials and Their Use," contains a detailed discussion of the materials used in the manufacture of these appliances and presents valuable technical data concerning leather, steel and its use in orthopedics, aluminum, plastic materials, rubber, adhesives, plaster of paris, wood, industrial sewing machines in orthopedic work, tools and machines commonly used by orthopedic limb and brace makers, and engineering considerations in the design of orthopedic appliances.

Other major parts of the book consider anatomy and physiology in relation to the prescription, construction, and fitting of orthopedic appliances as well as various types of appliances that are used for the spine and trunk, upper extremity, and lower extremity. Other parts of the book are devoted to braces for the paralytic patient and to the measurements of joint motion and that of parts of the body to which a brace, splint, or prosthetic device is to be applied.

This book is probably the first such comprehensive text in the English language and is a reference book which should be in the possession of every orthopedic surgeon, physiatrist, and orthopedic appliance maker as well as any other physician concerned with the use of orthopedic appliances.

The Doctors Jacobi. By Rhoda Truax. Cloth. $3.50. Pp. 270. Little, Brown & Company, 34 Beacon St., Boston 6, 1952.

This is a warmly written, well-paced story of Dr. Abraham Jacobi, famous American pioneer pediatrician known widely in New York during the last decades of the nineteenth century as "the doctor who saves the babies," and of his wife, Dr. Mary Putnam Jacobi, who studied pharmacy in New York and medicine in Philadelphia and had the distinction of being the first woman to gain admission to the École de Médecine in Paris. The biography of these two unusual people, the husband a refugee from European politics and poverty, the wife a daughter of the publisher G. P. Putnam, comes off exceptionally well, even though some of the dialogue and detail is fictionalized. This book falls "on that neutral ground between science and popularity" and is well worth the reading time of busy medical men and women.

How to Help an Alcoholic. By Clifford J. Earle. Cloth. $1.50. Pp. 96. Westminster Press, Witherspoon Building, Philadelphia 7, 1952.

By being matter-of-fact and emphasizing the practical aspects of alcoholism and its correction this volume provides inspirational guidance. The approach is one of broad appreciation and understanding and guides alcoholics to recognize and accept their roles and thus follow courses that are most likely to end in success. How alcoholism begins, clues for its early detection, and various treatment courses that may be followed are given instructive consideration. The chapter on guidance from recovered alcoholics and the 12 steps to recovery provide "treatment" material that may well be the turning point for many alcoholics. This small volume has universal applicability.

QUERIES AND MINOR NOTES

CARDIAC MASSAGE TO OVERCOME CARDIAC ARREST

To the Editor:—*Please outline the technique for entering the chest cavity for cardiac massage to overcome cardiac arrest during a surgical procedure. What treatment is established for surgical pneumothorax that follows as a result of this procedure?*

Thomas W. Kredel, M.D., Indiana, Pa.

Answer.—The important features in dealing with such a complication are (*a*) speed in instituting the cardiac massage and (*b*) the prevention and control of ventricular fibrillation if it should occur. To accomplish these objectives it is necessary that good exposure of the heart be rapidly obtained. Some surgeons prefer to incise the left half of the diaphragm and to enter the thorax in that way if the complication occurs during the course of an abdominal operation. Such an approach, however, does not give very satisfactory visualization of the heart and makes very difficult the application of an electric shock, if needed, to control ventricular fibrillation. It seems better, therefore, in all cases to approach the heart through an intercostal incision in the fifth or fourth left interspace. A rib spreader should then be applied in order to make the exposure of the heart adequate. Care should be exercised to avoid cutting the left internal mammary artery, which ordinarily lies within about 1 cm. lateral to the border of the sternum. After the chest wall is closed the lung should be reexpanded. This can best be accomplished by inserting two tightly fitting catheters, one anterior and one posterior, into the chest cavity to provide underwater drainage. Such a procedure will remove not only the air but also the fluid that always forms after an intrathoracic procedure. It is important to carry out the intrathoracic operation with endotracheal anesthesia. If no facilities for such anesthesia are available the use of a tightly fitting face mask may be substituted, although it is not as satisfactory as endotracheal anesthesia.

LOW BLOOD SUGAR LEVEL

To the Editor:—*A patient has a persistently low blood sugar content (67.5 mg. per 100 cc.). What could be the reason for this condition, and what can be done to correct it? Except for a feeling of weakness, he has no symptoms.*

Heinrich F. Wolf, M.D., New York.

Answer.—A blood sugar level of 67.5 mg. per 100 cc., whether fasting or at any time during the day, is a mild degree of hypoglycemia. It may have no significance, but it could be due to actual or relative hyperinsulinism, the opposite condition to diabetes. Fatigue or worry in the presence of adrenal deficiency may cause spontaneous hypoglycemia. Perhaps the patient is overworked or worries too much; if so, more rest and less worry may correct the condition. The excessive use of sweets, such as desserts, candy, or soft drinks, may cause hypoglycemia by stimulating an excessive secretion of insulin by the pancreas. The patient should reduce the cane sugar products in his diet. A high protein diet, i. e., one providing meat two or three times a day and cheese or peanut butter with crackers taken three hours after meals, is helpful in such patients who are underweight or of average weight. If the patient is overweight, he should eat not more than one slice of bread at a meal, an egg for breakfast, lean meat for luncheon and dinner, with large servings of green vegetables, and medium servings of yellow vegetables, such as carrots and turnips. Fruit juice—orange, grapefruit, or apple juice—should be given on awakening, three hours after meals, and at any time for weakness. If the symptoms persist, a six hour glucose tolerance test is indicated to determine whether the patient has actual or relative hyperinsulinism.

SLIPPED FEMORAL EPIPHYSIS

To the Editor:—*A 15-year-old boy has a slipped femoral epiphysis that has rotated so that the head is almost entirely off the neck of the femur. His symptoms began 18 months ago. For six weeks he has been unable to walk. He has an atypical Frölich's syndrome. There is no involvement of the other hip. Do you think the position of the head could be improved by traction? Roentgenograms show the epiphyseal line to be still present, and fusion has not taken place. If the position has improved after 6 to 12 weeks of traction and the head has not fused, do you think the use of a Smith-Petersen nail would be indicated?*

M.D., Minnesota.

Answer.—After 18 months' duration of this condition, traction on the leg would not change the position of the capital epiphysis. Skilfully applied manipulation, with the patient under anesthesia, may effect a change of position. If so, and if the restoration were considered satisfactory, a Smith-Petersen nail or suitable screw should be inserted, without splitting the head, for fixation of the head of the femur to the neck. If manipulation fails, open operation employing a cuneiform osteotomy, reposition, and nailing is indicated. Any shortening of the leg caused by an early fusion of the epiphysis thus obtained may be compensated for in part by overgrowth of the distal epiphysis. No surgeon except one highly trained in this type of work should attempt such an operation.

SIGNIFICANCE OF ARCUS SENILIS

To the Editor:—*What is the significance of a marked arcus senilis in a man 43 years old? Is there any relationship between it and atherosclerosis? Is it a sign of the aging process?*

M.D., Toronto, Canada.

Answer.—Arcus senilis is a form of lipoid deposition in the peripheral cornea; it is usually considered to be associated with senescence; however, the condition may occur early in life, and its appearance in the fourth decade is not uncommon. The relationship between arcus senilis and atherosclerosis is debatable. Boas (Arcus Senilis and Arteriosclerosis, *J. Mt. Sinai Hosp.* **12:**79 [May-June] 1945) found an appreciably higher incidence of coronary disease among those with arcus senilis than those without it. Garn and Gertler (Arcus Senilis and Serum Cholesterol Levels in the Aleut, *New England J. Med.* **242:**283 [Feb. 23] (1950) have disputed the relationship between arcus senilis and hypercholesterolemia discussed by Boas. They conclude that hypercholesterolemia or degenerative disease need not be a concomitant of arcus senilis.

EPISTAXIS AND HEART DISEASE

To the Editor:—*Since having an attack of coronary occlusion, a patient has been using neocurtasal® (a sodium free salt substitute consisting of potassium chloride, ammonium chloride, potassium formate, calcium formate, magnesium citrate, and starch), but he has had nose bleeding. Do you think the blood vessels are more fragile after neocurtasal® has been used?*

M.D., Illinois.

Answer.—Epistaxis is a common occurrence in patients with heart disease, especially when there is associated failure, hypertension, or rheumatic fever. Since it is stated that the patient had an attack of coronary occlusion, and neocurtasal® was then prescribed, presumably there was an episode of congestive failure. Neocurtasal,® which is primarily a salt of potassium chloride, is used as a substitute for salt, so that the ingestion of sodium ion may be restricted. There has been no evidence to suggest that this compound will cause increased capillary fragility that might lead to bleeding of any type. If nosebleeds are severe and occur especially from a single site, a small ulcer or erosion should be sought and if found should be treated by application of a simple chemical (silver nitrate) or electric cautery.

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any official bodies unless specifically stated in the reply. Anonymous communications and queries on postal cards cannot be answered. Every letter must contain the writer's name and address, but these will be omitted on request.

STIMULATION OF SPERMATOGENESIS

To the Editor:—*A man two years ago had a sperm count of 1 million per cubic centimeter, and a total semen volume of 3 cc. Results of a testicular biopsy were normal. He was given small doses of methyltestosterone, and almost complete suppression of spermatogenesis occurred. Would it be possible at present for him to have a sperm count high enough to produce a pregnancy? If pregnancy in such a case occurs, would the baby be normal?* M.D., *Ohio.*

Answer.—Testosterone may be used in the treatment of oligospermia with some hope of success if testicular biopsy shows that no irreversible changes have taken place in the germinal epithelium. Large doses are employed—50 mg. administered parenterally 3 times a week up to a total dose of 2,000 mg. or more. The initial effect is a depression in spermatogenesis leading to complete or almost complete azoospermia, but some time after therapy is discontinued a majority of the patients exhibit a "rebound" phenomenon, with sperm counts rising well above the pretreatment levels. A few of them succeed in impregnating their wives. On the other hand, in about 15% of cases the depression is not followed by a rebound, and the patients may be in a worse condition than they were before. Small doses of testosterone can depress spermatogenesis, as occurred in this case. When they are discontinued, the previous seminal values are usually restored, with no benefit accomplished and no permanent damage done.

While impregnation sometimes occurs with notably low sperm counts, in general, any reduction in numbers below the conventional figure of 60 million spermatozoa per cubic centimeter involves a corresponding reduction in relative fertility. For this reason oligospermia should be treated. In the present case it might be worth while to try the large dose testosterone method. Adjuvant measures include attention to the general health and hygiene, a high protein, high vitamin diet, and enough thyroid to keep the basal metabolic rate at or a little above the +10 level.

An alternative method for impregnation would be the preparation of a centrifuged sperm concentrate and application of this to the cervix either with a syringe or in a plastic cervical cap. The rate of miscarriage of first pregnancies among couples relieved of sterility is slightly higher than in the general population. If this hazard is escaped, the chances of having a normal baby at term will be the same as they are in other matings.

METHANTHELINE BROMIDE AND VISION

To the Editor:—*Can methantheline bromide (banthine®), 50 mg., given at bedtime, cause continued blurred vision, "circles" under the eyes, and twitching of the eyelids in a male patient 41 years of age who apparently has normal vision?* M.D., *Ohio.*

Answer.—Methantheline bromide (banthine®) causes a cholinergic blockade and will affect accommodation, if the dose is large enough, in a manner similar to atropine. When instilled into the conjunctival sac it causes pupillary dilation and cycloplegia and has an action similar to that of homatropine. It seems possible, therefore, that methantheline bromide may cause blurring of vision, severer for near objects than for distant objects, and that twitching of the eyelids may be associated with this.

FRECKLES

To the Editor:—*What are the etiology and pathogenesis of ephelides? Are there any studies on the treatment of ephelides with cortisone and corticotropin (ACTH)?*

Nehmet H. Nagle, M.D., Turkey.

Answer.—Ephelides, or freckles as they are commonly called in this country, are due to precipitation of pigment in localized patches caused by exposure to sunlight. This is often a family trait, seen mostly in blonde and redhaired persons, although it occurs also in the mulatto. Cortisone and corticotropin (ACTH) have been found to be of no value in the treatment of this condition. It is possible by the use of monobenzyl ether of hydroquinone to reduce the number of freckles temporarily.

TESTOSTERONE AND THE MALE CLIMACTERIC

To the Editor:—*In a question and answer column in a medical periodical the answer stated that giving testosterone to uncastrated elderly men seems most unwise, and that whether the "male menopause" actually exists is open to question. My reading on the subject does not coincide with this viewpoint. I would appreciate having your opinion on this subject.*

E. W. Goldstein, M.D., Pittsburgh, Pa.

This inquiry was referred to two consultants, whose respective replies follow.—Ed.

Answer.—There is a difference of opinion as to the actual existence of a condition in the elderly man comparable to the female menopause. There is not much doubt, however, that many elderly male patients develop definite psychogenic symptoms, which apparently result from changes in glandular physiology and sex hormones. Although many of these patients are definitely helped by administration of testosterone, there are others in whom androgenic therapy has no effect. Whether beneficial results from testosterone are brought about by its action as a metabolic hormone or as a sexual hormone has not been definitely determined. It should be stated, however, that long-continued treatment with testosterone in large doses might have injurious effects. Cases have been observed in which there is apparently carcinogenic action in prostatic cells.

Answer.—There is still some difference of opinion on this question; however, most of the data available indicate that giving testosterone to older men will not in itself cause carcinoma of the prostate. It may perhaps accelerate the growth of a carcinoma already present, but androgen alone will not cause normal tissue to become carcinomatous. There is enough evidence available to demonstrate that there is a male climacteric, which responds specifically to androgen therapy; however, it is not nearly as common as the menopause in the woman, and great caution must be used in arriving at the diagnosis.

STERILIZATION OF SYRINGES

To the Editor:—*Is the practice of rinsing syringes and needles in acetone or ether a satisfactory method of cold sterilization? If not, what is the preferred cold method for use by the general practitioner?*

Newton H. Reid, M.D., College Park, Md.

Answer.—The risk of causing homologous serum jaundice precludes the use of any chemical agent for disinfection of syringes and needles. There is no evidence that such agents are effective in preventing the transmission of the virus. Immersion in boiling water for 15 minutes or dry heat sterilization for an hour at 165 C (329 F) is recommended for the disinfection of previously cleaned lancets, needles, and syringes.

DISCREPANCIES IN BLOOD CELL COUNTS

To the Editor:—*I have noted discrepancies in blood cell counts performed by different laboratories. I find that one laboratory makes all red blood cell counts and hemoglobin determinations from venous blood. Another uses both venous and capillary blood, and another uses only capillary blood. Are variations in blood cell counts to be expected and, if so, to what degree?* *John T. Hecker, M.D., Cedar Rapids, Iowa.*

Answer.—From a practical standpoint, no great differences will occur between hemoglobin determinations and red blood cell counts made from venous blood and those made from capillary blood. In regard to white blood cell counts, blood from the capillaries may give somewhat higher values (1,000 to 1,500 cells per cubic millimeter) than venous blood. The discrepancies in blood cell counts performed by different laboratories are not due to differences in the location from which the blood is obtained but are the result of the great variation in accuracy and techniques existing in the different laboratories. The various factors contributing to these discrepancies are discussed in the Syllabus of Laboratory Examinations in Clinical Diagnosis (Ham, T. H., editor, Cambridge, Mass., Harvard University Press, 1950).

BRONCHIECTASIS

To the Editor:—*A 45-year-old white woman had a lobectomy for bronchiectasis two years ago. She now has bilateral involvement. Her condition remains about the same with bed rest, supportive treatment, and terramycin, 250 mg., every six hours. Without terramycin, she runs a low-grade fever. Would penicillin-sulfonamide therapy or penicillin inhalation be of any value?*

Robert L. Bestoso, M.D., Newport, R. I.

Answer.—If complete bronchograms have not been obtained since operation, these should be done to determine the distribution of the remaining bronchiectasis, since certain cases, even when the disease is bilateral, are considered for surgical resection on the second side. If the distribution of the bronchiectasis in this patient is such that surgery can no longer be considered, then the objectives of treatment should be (1) to improve drainage from the bronchial tree, and (2) to eliminate infection with antibiotics. The first objective necessitates postural drainage, performed at least twice daily; undoubtedly periodic bronchoscopic aspiration would likewise be helpful in preventing stagnation of secretions. Reasonable physical activity should be allowed, unless this results in temperature elevation or undue fatigue.

Antibiotic treatment is preferably based on laboratory determination of the susceptibility of the organisms found in the sputum or, better, in secretions obtained at the time of bronchoscopy. It appears likely that systemic administration of antibiotics is more effective than administration by inhalation alone; however, for maximum effect, combined administration (systemic and inhalation) is preferred, about one-third of the total daily quantity being given by the latter method in four divided doses. Empirical use of a sulfonamide, such as gantrisin® (3,4-dimethyl-5-sulfanilamido-isoxazole) would be justified if response to antibiotics is not satisfactory. Usefulness of maintenance doses of antibiotics entails the problem of induced resistance of the organisms present, so that intensive treatment for periods of 7 to 10 days, preferably combined with bronchoscopic aspiration, followed by an interval without specific antibacterial treatment, would seem more rational.

PLASTIC INDURATION OF PENIS

To the Editor:—*About eight months ago a plastic induration on the middle of the urethral surface of the penis developed in a patient. At that time the involved area was treated with filtered roentgen rays, and the induration was greatly reduced. Later, the patient was given ten ultraviolet ray treatments, which helped somewhat. Now the induration is as large as it was before treatment. This is the first such case seen during my long practice, and I will appreciate your opinion on treatment and prognosis.*

Angelo Marcoglous, M.D., Greece.

Answer.—This patient has Peyronie's disease, which is sometimes called plastic induration of the penis and, also, fibrosis of Buck's fascia. The treatment of this condition is very discouraging. Diathermy and other types of local heat application over a long period of time have in some instances produced a softening of the scar tissue. Treatment with continuous doses of vitamin E in the form of eprolin® (a concentrate of natural alpha, beta, and gamma tocopherols) or tocopherol acetates, 100 to 200 mg. given 2 to 3 times a day, has in a few instances resulted in regression of the induration. This has been especially true in the patient who has Peyronie's disease and Dupuytren's contracture of the fingers simultaneously. Ultraviolet or infrared ray treatments should not be used. The best improvement to date has occurred with treatment by local irradiation with combined roentgen rays and radium topically applied by an experienced radiologist. Recently, injections of solvent material, such as hyaluronidase, have been tried, without appreciable permanent improvement. Almost every type of treatment has been used, including futile surgical attempts at incision and extirpation. The disease often disappears or improves spontaneously with no treatment. The only logical treatment, used by those who see many of these patients, is a 6 to 12 month course of vitamin E therapy and local irradiation. The lesion never becomes malignant as far as is known. This disease was thought to be rare some years ago, but in the United States, at least, it occurs in about 1% of all men over the age of 55.

TUBERCULOUS LYMPHADENITIS

To the Editor:—*A woman, aged 45, with two children, had an enlarged cervical gland under the right sternocleidomastoid muscle in 1936. It was the size of an orange. Guinea pig inoculation of material obtained surgically revealed tuberculosis. There was no recurrence until 1951, at which time the family moved from southern to northern California. The gland is now the size of a walnut. Chest roentgenograms show no tuberculosis. Roentgen therapy of the gland is being considered as the patient refuses any kind of biopsy. Is a tuberculous cervical lymph gland influenced in any way by dampness?*

Willis J. Bogue, M.D., Chico, Calif.

Answer.—The question of the influence of "dampness" on cervical lymph nodes is not of great importance. Dampness may cause frequent "colds," chilling, and "lowering of resistance," but the existence of a previous infection is the chief concern. The fact that the patient had a tuberculous node removed many years ago leaves little doubt about the nature of the process, since such infections may "smolder" for many years. The treatment should be that for a tuberculous node, at least until such treatment fails to be effective. In that event, a biopsy may be mandatory. X-rays can be used successfully on early tuberculous nodes, but the best treatment is the combination of streptomycin (1 gm. twice a week) and *p*-aminosalicylic acid (PAS) (12 gm. a day in four doses). If the nodes are soft and large, surgery may also be necessary.

SENSITIVITY TO RABIES VACCINE

To the Editor:—*Is there a satisfactory way to test sensitivity to rabies vaccine?*

George A. Peck, M.D., Salt Lake City.

Answer.—There is no reliable method for testing sensitivity to rabies vaccine. It has been presumed that severe reactions, when they occur, are due to the presence of the rabbit brain tissue in the vaccine. The frequency with which antirabies vaccination accidents occur is commonly overemphasized. Their occurrence has been variously stated to be from 1 in 9,000 to 1 in 600 persons (Los Angeles, 1940 to 1946). The problem of rabies vaccine reaction is discussed in "Correction of Summary on Rabies in 1951—Report of the Academy (of pediatrics) Committee on Immunization and Therapeutic Procedures for Acute Infectious Diseases" (*Pediatrics* **9**:336 [March] 1952).

MUMPS VACCINE

To the Editor:—*Is material for skin testing for determining immunity to mumps available? If a skin test or complement-fixation test is negative in an adult male, would you recommend using Hyland's hyperimmune mumps serum?*

Etta Link, M.D., Berkley, Mich.

Answer.—Material for skin testing for susceptibility to mumps is now available (Lilly). Mumps vaccine is also used for active immunization that is presumed to endure for six months to a year. The skin test is believed to be more reliable for adults than the complement fixation test. The latter is preferred in the case of children. Hyperimmune mumps serum for passive immunization is considered to be of value by some investigators. When used in large doses for treatment it is thought to reduce the frequency of orchitis.

PROTECTIVE GOGGLES

To the Editor:—*Could headache or dizziness result from the use of work goggles with clear or colored lenses, which are not fitted by prescription, by men who do not ordinarily wear glasses?*

J. M. Hesser, M.D., Benson, Ariz.

Answer.—Protective lenses will not cause headache or dizziness unless a prism or cylinder is ground into the lens. If the lenses are without power they should have no action other than reducing the amount of light entering the eyes. Sometimes safety goggles, because of their weight, cause head pains if the frame has been improperly fitted.

DIAGNOSIS AND TREATMENT OF EPILEPTIC AND EPILEPTOID DISORDERS

Nicholas A. Bercel, M.D., Beverly Hills, Calif.

The subject of epilepsy is important in general practice since a little more than one out of every three private epileptic patients is treated by the general practitioner. The disease is as common as tuberculosis or diabetes. Although accurate descriptions of this disease have been available since biblical times, progress in diagnosis, let alone in treatment, began in reality only in 1870, when Jackson published his study on convulsions. The elusiveness of the diagnosis already plagued the ancient Romans, who were prompted to use tests by which attacks could be provoked artificially in slaves who were on sale. The difficulties of treatment were already known in the 19th century, when Esquirol put three epileptics in the hospital and tried one treatment after another, each different, on the same patient; every treatment was effective for a short time, but none brought about a lasting cure.[1] Even though a tremendous amount of progress has been made during the past 80 years, it seems that every new diagnostic device and every new anticonvulsant drug has added as many problems as it had solved.

DEFINITION AND INCIDENCE

"Convulsion" implies a motor element, which may be absent in most of the attacks; only 25% of seizures are generalized tonic-clonic motor fits, commonly called grand mal, while 71% consist of short-lasting disturbed states of consciousness, called petit mal, and only 3% of the attacks are described as psychomotor.[2] Epilepsy is a condition characterized by repetitious attacks. A single seizure, therefore, is not—although it may turn out to be—epilepsy. A good physiological definition of epilepsy is a tendency to "periodic involuntary neuronal explosions, most often resulting in either disturbed state of consciousness or motor release phenomena," [2] or various combinations in various degrees of both. Seizure is a term covering all forms of the epileptic attack and does not carry the prejudicious connotation that epilepsy does. Roseman's [3] definition, "a state of continuing dread interrupted by recurring attacks of involuntary behavior," ought to be preferable, being both realistic and comprehensive.

CAUSATION

In three out of four cases, the underlying cause is either unknown or unreliable; this kind of epilepsy is called idiopathic or essential. When the cause is known, one out of four, the condition is termed secondary or symptomatic epilepsy. Petit mal is more prevalent in infancy and childhood. Psychomotor epilepsy is most prevalent between the ages of 15 and 35. Grand mal, on the other hand, can occur at any time, at any age. The commonest idiopathic history consists of petit mal in the first five years of life, continuing with variable frequency up to adolescence, when it is replaced by or mixed with grand mal. In the majority of cases the epilepsy is idiopathic up to the age of 20. Tumors, infections (encephalitis and abscess), and hematoma are important causes between 20 and 40 years, whereas, after the age of 40, cardiorenal disease and cerebral vascular accidents will become increasingly frequent causes. Febrile convulsions are not uncommon between the ages of 1 and 3 years, and one out of five children with febrile convulsions will later become epileptic.

The over-all incidence of hereditary epilepsy is less than it is feared—a fraction of 10%. Lennox, Gibbs, and Gibbs, however, demonstrated about 60% abnormality in the brain wave records of blood relatives of epileptics, as contrasted with the 10% of the control group, who had no near relative with epilepsy. It is commonly thought that, however abnormal the brain wave record of an epileptic parent's child may be, if he did not have recurring convulsive attacks up to the age of 21, it is wholly unlikely that he will ever be afflicted with idiopathic epilepsy. The inheritance of abnormal brain waves might (but need not) be interpreted as a predisposition to epilepsy. The chances of a child's having epilepsy, if one parent is epileptic, is 1 out of 40, with a rising probability ratio when both parents are so af-

flicted. These figures should be made available to those epileptics who so often want to put the decision of marriage and of having children up to the physician. While there may be a question about the advisability of marriage and family creation when both parties to the union are epileptic, counseling against it when only one partner is epileptic is more of a reflection on the insecurity of the adviser than a realistic appraisal of the facts as we know them today.

Birth injury, or birth anoxia, is probably a more important factor than is commonly realized. Nielsen[4] claimed that more than 50% of epileptics are first-born children, whose heads are subjected to the often traumatizing task of dilating the birth canal. Painstaking control of the anesthesia during delivery as well as better care of the newborn child and its respiratory problems could eliminate this unnecessary potential source of epilepsy.

Since the electroencephalogram can demonstrate central nervous system complications even in benign infections, such as infectious mononucleosis,[5] and since the same test done serially in a postacute period can point out focal potentially epileptogenic residuals, much of the guesswork surrounding the role of encephalitis can be done away with. Extension to the brain of the commonest childhood infections, especially scarlet fever, smallpox, influenza, measles, and typhoid, is fairly frequent. Sinus and middle ear infection used to supply a large percentage of abscesses, half of which predictably resulted in epilepsy. This is rapidly becoming a thing of the past, owing to the use of antibiotics.

Cerebral trauma, not counting subdural hematoma, is another important source. About 35% of dura-penetrating brain injuries—so common in war time—will result in post-traumatic epilepsy, while, in closed head injuries, the figure is much lower, none of the statistics going over 5%. Why so few patients with closed head injuries (which are very common) experience seizures might find an explanation in inherited cerebral dysrhythmia, which makes one more vulnerable to an accidental blow on the head. In brain trauma, serial electroencephalograms can monitor the clinically invisible state of events, pointing out the danger when post-traumatic seizure discharges make their appearance, which would even justify prophylactic anticonvulsant medication during the critical first two years following head injury, when the majority of post-traumatic epilepsies occur.

In any adult, when seizures supervene for the first time after the age of 20, cerebral neoplasm has to be looked for with bulldog tenacity. Two out of three tumors of the hemispheres result in seizures. Among the tumors most commonly causing seizures, seizure was the initial symptom in 68% of cases of astrocytoma, in 60% of meningioma, and in 51% of glioblastoma.[6]

DESCRIPTION

The contributions of electroencephalography and neurosurgery (experimental neurophysiological studies on the human) have changed our thinking with respect to the various seizure types and their origin. Grand mal is often preceded by an aura that is part of the seizure and usually indicates that the epileptogenic focus is in the cerebral cortex. These auras either are patterned (indicating successive detonation of neighboring cortical areas), e. g., the Jacksonian march, or are focal seizures, which in turn might involve motor functions (of the eyes, head, limbs, and mastication) or sensory functions (somatic, visual, olfactory, and auditory sensations). Dizziness and a variety of psychical seizures associated with disturbed consciousness and automatic behavior may appear as the forerunner of an attack. Such seizures, if they occur without the generalized motor follow-up, are classified as minor or focal seizures. Petit mal is characterized by momentary loss of consciousness, although there may also be a few minor flickers of the eyelids, usually three per second, or jerks of the arms. These attacks rarely last longer than 30 seconds. It is customary to include in the petit mal triade the myoclonic jerk and the akinetic seizure consisting of loss of postural control. Seizures initiated by loss of consciousness, or consisting of loss of consciousness only, are referred to as highest level seizures. Penfield and Jasper[7] stated that

> . . . the opinion has been held traditionally that the highest level in central nervous system hierachy is to be found in the more recently acquired areas of the cortex, those areas which serve to distinguish the brain of men from that of the ape. Experimental and EEG data suggest that the frontal lobe is not the highest level, but that in the subcortex (particularly in some of the thalamic nuclei near the midline) there is a collection of nerve cells with ready access to all parts of the cerebral cortex which, when a neural discharge originates in them, will lead to instantaneous suspension of the conscious processes.

Psychomotor seizures are characterized by transient lapses of consciousness of different degrees accompanied by automatic behavior. They are often preceded by smacking of the lips, masticatory movements, and temporary arrest of speech. It is now believed that these seizures are focal in origin and that the focus is usually in or near the tip of the temporal lobe. Automatic behavior is a dangerous aspect of epilepsy, since, in this state, without the censorship and control of consciousness, the patient can engage in actions that may be violent and even homicidal. Many of such patients have been placed in state hospitals with false diagnoses, for which mistake there can be little excuse nowadays, since the electroencephalogram, particularly done while the patient is asleep, will pinpoint the characteristic psychomotor patterns and will make them available for medical or surgical treatment.

As the clinical and experimental material with respect to cortical localization accumulates, the baffling variety of conditions under which an epileptic attack can masquerade becomes more and more evident. The following conditions were found to be in reality minor epileptic attacks: paroxysmal abdominal pain, coronary occlusion, periodic mental dulness, anxiety hysteria, renal or biliary colic, acute appendicitis, Ménière's syndrome, syncope, paroxysmal perspiration, aphasia, blindness, migraine, criminal psychopathic behavior, schizophrenia, manic-depressive psychosis, primary behavior disorder, hysterical fugue, enuresis, and nymphomania. One ought to be, therefore, sensitized to the fact that, whenever one deals with an attack that does not fit into the usual clinical picture, more particularly one that is refractory to proved accepted forms of treatment, its epileptic nature should be suspected and confirmed or ruled out by electroencephalographic study.

[7] Penfield, W., and Jasper, H.: Highest Level Seizures, in Association for Research in Nervous and Mental Disease: Epilepsy, Baltimore, Williams & Wilkins Company, 1947, pp. 252-271.

It is reliably estimated that 65% of children with behavior problems have abnormal records, as compared with a corresponding figure of 16% in a control group. The assumption is that there is similarity between the electroencephalographic pattern of the epileptics and of these children with behavior disorders, and that the symptoms of both groups are due to sudden periodic cerebral cortical changes.[8] The majority of these records show some form of paroxysmal dysrhythmia even though the true spike, or wave and spike, explosions of the classical epileptic are rarely encountered. Antiepileptic treatment, at times successful, has not reached a degree of reliability so that it could be used as a diagnostic counterproof. Since, however, periodic explosive behavior can be a form of epilepsy, the use of electroencephalograms in all cases of behavior disorders is justified, particularly when expensive long-term psychotherapeutic management or segregation in special classes is contemplated.

TREATMENT

Treatment of epilepsy—as of diabetes and tuberculosis—is a long-term program. Owing to the unpleasant and (to the uninitiated) frightening nature of an epileptic attack, the physician is often placed under a considerable amount of pressure on the part of the family or the patient to terminate the attack as soon as possible. This is not the primary aim of treatment, nor is it to use as few pills a day as possible. The general therapeutic principles can be expressed in the following way:

1. Finding the most suitable anticonvulsant and its right dose requires an average of six months. 2. One should start out with the best established drug that has proved its value and increase the dose slowly, in order to avoid the toxic effects that are common at the beginning of treatment with a new medicament or when the dose is increased suddenly. 3. One should change to newer medications only when the older ones used in adequate near-toxic doses have consistently failed. The more recent a drug, the more toxic it is, which means that precautionary laboratory examinations will also make them more expensive. 4. One should not follow fixed formulas; anticonvulsant medication has to be tailor-made. 5. Epileptics do not live on drugs alone. With these principles in mind, approximately 70% of all epileptics who have seizures can be successfully controlled or the seizure incidence decreased to the minimum.

Bromide.—This drug, introduced in 1853, was the first successful anticonvulsant. It is used chiefly in institutionalized epileptics. It appears that the side-effects of bromide medication have been exaggerated and the virtues neglected. The therapeutic dose is 5 to 15 grains (0.30 to 1 gm.) of the sodium or the triple salt, given two or three times a day.

Phenobarbital Sodium.—Phenobarbital sodium, introduced in 1912, still one of the best standbys, is quickly effective if taken on an empty stomach; on the other hand, the action lasts longer if it is taken after meals. The average dose is 1½ grains (0.10 gm.), taken three times a day, a single dose giving protection for approximately 6 to 12 hours. The commonest cause of status epilepticus (continuous seizures) is sudden cessation of phenobarbital medication. Bromides and phenobarbital sodium have a sedative effect, which varies from patient to patient.

Diphenylhydantoin Sodium.—A great landmark in modern treatment of epilepsy was the introduction of the use of diphenylhydantoin (dilantin®) sodium by Merritt and Putnam, in 1938. This drug (either the sodium salt or in oil), considering its low toxicity and high efficacy, is the best available anticonvulsant. It should be given after meals, with a single capsule of 1½ grains at the start and the dose increased by one capsule every week, until either signs of toxicity appear or seizures are controlled. By the time six capsules, in equally divided doses, are given a day, if seizures continue, one should consider combining this treatment with the administration of 1½ grains of phenobarbital sodium, particularly at nighttime, rather than increase the dose. Gradual increase until the effective dose is reached is the best safeguard against the toxic reactions, consisting of ataxia (some patients have been arrested for drunkenness), drowsiness, blurring of vision, morbilliform rash, gastric distress, and hirsutism. Hypertrophy of the gums occurs more often; massaging with rubber tooth brushes, strict dental care, and occasional surgical removal of the protruding excess gum is advisable. Because of the slow decomposition of the drug in the system, it can also be given in the morning, all at once.

Trimethadione.—The drugs so far mentioned have comparatively little effect on the petit mal triad. In fact, in some patients these minor seizures might be aggravated by the administration of diphenylhydantoin alone. The introduction of the use of trimethadione (tridione®), by Lennox, Richards, and Perlstein, constitutes an advance in treatment for petit mal no less outstanding than the discovery of diphenyldantoin for use in grand mal. The dose should be one capsule of 5 grains (0.30 gm.) for infants, two capsules between the ages of 2 and 4, and three capsules from 5 years and upward. These amounts may be increased to a maximum of three times the above amounts. Among the toxic by-effects are sensitivity to light, particularly at the beginning, and drowsiness. Trimethadione is a potentially dangerous drug, because it depresses the hematopoietic system, and some fatalities from resultant agranulocytosis and pancytopenia are on record. These occurred as often at the beginning of as after prolonged medication. Gradual administration is again the rule. A biweekly and, later (after two months), a monthly complete blood cell count, including a platelet count, is a necessity. Should the neutrophil count, which often indicates an insignificant drop, reach 2,500, decrease in dosage or even temporary discontinuance of medication is advisable. Unfortunately, even blood cell count monitoring may not give a sufficient warning, because of the insidious nature of neutropenia, for which reason this drug should not be given to patients who have a history of allergic hypersensitivity to other drugs. It seems that trimethadione given alone will aggravate grand mal seizures. In patients with mixed seizures, therefore, it is well to combine trimethadione with either phenobarbital sodium or diphenylhydantoin sodium.

Paramethadione.—For those who are refractory to trimethadione medication, an allied preparation called paramethadione (paradione®), given in similar doses might be of value, it being clearly understood that the same precautionary measures must be observed. Paramethadione therapy is effective in cases of "highest level" seizures. Approximately 80% of patients with petit mal will show a good response to medication with the "diones."

Methylphenylethyl Hydantoin. — Methylphenylethyl hydantoin ("mesantoin") has been recently introduced and found to be efficacious in patients who fail to respond to diphenylhydantoin sodium therapy. The mode of administration and the dose are those identical with the latter drug, but, because of its relatively greater toxicity, special emphasis should be placed on slow, gradual increase to the effective dose, e. g., one-half tablet per week. Sleepiness is a common side-effect, while lymphadenopathy, morbilliform rash, exfoliative dermatitis, and neutropenia have occasionally occurred. A few cases of fatal blood dyscrasia have also been reported. As with diphenyldantoin sodium, it is best to add phenobarbital sodium if six tablets of methylphenylethyl hydantoin per day fail to produce the desired effect. Experience indicates its efficacy particularly in cases of grand mal and Jacksonian convulsions, with less effect in cases of other forms of seizures.

Phethenylate Sodium and Phenacemide.—Phethenylate ("thiantoin") sodium and phenacemide (phenurone®), two newer drugs, are also available. The latter is especially effective for psychomotor attacks, but, besides blood cell counts, liver function tests are a necessity for the detection of liver damage, which occasionally occurs.

Other Forms of Treatment.—In status epilepticus, slow intravenous injection of phenobarbital sodium, amobarbital sodium, vinbarbital ("delvinal") sodium, paraldehyde, and trimethadione is of definite value. Diphenylhydantoin sodium can also be given, through a stomach tube, along with fluids, electrolytes, and nutrients. In the refractory cases, sometimes heroic measures are needed; one has to diverge from the beaten track. Thus the use of amphetamine sulfate often helps in petit mal cases, as does the introduction of gas in the subarachnoid space by means of ordinary pneumoencephalography. Electric convulsive treatments—which raise the convulsive threshold after each seizure—were used not only with impunity but with success when everything else failed. Carbon dioxide inhalation has also been tried and has been of value. Putnam and co-workers[9] advocated "hyperintensive" treatment either with continued barbital narcosis or with toxic doses of the whole battery of anticonvulsants given on successive days; the physician should then choose the combination of drugs as a steady regimen that most improves the electroencephalogram.[9] Some drugs given in toxic doses, paradoxically, increase the electroencephalographic seizure pattern; their use should be abandoned altogether. The underlying philosophy of these special measures is the same: one's ingenuity should never concede defeat to epilepsy.

Because of technical difficulties, ketogenic diet and the administration of glutamic acid are not in great favor. Food substances producing alkalosis should be decreased and replaced by a diet that produces acidosis. The use of alcoholic beverages in any amount is absolutely contraindicated in successful treatment of epilepsy.

Surgical treatment (consisting of removal of posttraumatic scars and subpial resection of atrophied gyri) has been advocated in cases in which medical management, after a conscientious trial, has failed. In cases of refractory psychomotor epilepsy, good results may be obtained with the recently developed temporal lobectomy, which is not as yet universally adopted, although preliminary reports show encouraging results.[10] According to these, unilateral electroencephalographic spike focus, organic pathological changes, absence of rage, and good interseizure personality are related to the best postoperative results.[11]

Poor cerebral circulation due to inadequate blood flow and oxygenation is receiving increasing attention. Breathing exercises as well as any form of physical exercise are to be encouraged, even though some patients are sensitive to the results of overventilation. If they can be taught to control their breathing and therefore keep carbon dioxide from being dissipated, the nonviolent sports are permissible. Improvement of general circulation and accumulation of lactic acid with exercise are the advantages that far outweigh the small statistical probability of bringing about a seizure owing to overbreathing. Although the exact mechanism is not known, emotional upset and sudden discharges of intense affect at times will initiate an attack in the epileptic.

COMMENT

While statistics indicate that only 18% of colleges in the United States refuse admittance to epileptics,[12] only 48 per 1,000 epileptics attend college. If this is due to unofficial discrimination, this cannot find justification in the assumption that epileptics as a group have a lower I. Q., because, as a matter of fact, 65% of them have above average intelligence.

While epileptics should not be encouraged to engage in occupations where they are exposed to danger by machines, the blanket refusal of occupation in factories and stores is not justified. The personnel offices of most large firms submit a questionnaire in which the occurrence of epileptic seizures is prominently displayed. At present, many an epileptic has to perjure himself and run the risk of refusal of compensation in case of accident if he wants to make a living.

In certain states, such as California and New Jersey, it is mandatory that the physician notify the authorities whenever he handles an epileptic. There is no statistical evidence indicating that a larger percentage of epileptics are subject to traffic accidents than are normal persons. While it is good practice to prohibit driving, exceptions should be made in the cases of well-controlled, nondrinking, conscientious, and intelligent patients, and such factors as sufficient warning, strictly nocturnal attacks, and rare seizures should receive proper consideration. In some states, the personnel of the motor vehicle department judge every case on its own merit, with ample advice from and cooperation with the treating physician. A partial solution to this problem might be the issuance of temporary driver's licenses, renewable every three or six months, after recheck by the treating physician. One would welcome a comparable zeal on the part of authorities if they were to clear the highways of recidivant alcoholic drivers, a far greater potential source of accidents.

Friendly, trustworthy cooperation between physician and patient is of great importance in cases of epilepsy. The International League Against Epilepsy is an effective alliance among physicians, patients, and lay groups, which is exerting an unceasing effort to better the unenviable lot of the epileptic. Every physician should encourage his patient to join the league and use his influence to promote this remarkable enterprise.

It cannot be hoped that the lot of the epileptic can be successfully improved until every physician, particularly the general practitioner, undertakes an educational role in his community in order to change prevailing public attitudes. The following statistics are from a recent public opinion survey[13] on a national scale: 50% of persons interviewed had actually witnessed a seizure; school and play participation by epileptics was approved by over half and objected to by one-quarter; employment was advocated by 45% and objected to by 35%. While this reflects a significant progress in the understanding and acceptance of persons subjected to convulsive disorders, there still prevails enough ignorance about the epileptic, particularly in small communities, to amount to a dark stigma, which is just as undeserved as it is unjustified. The aim of treatment in epilepsy, therefore, is not just control of the seizures but also assistance to the epileptic in his adjustment on a social and economical as well as educational level.

CLINICAL-ELECTROENCEPHALOGRAPHIC CORRELATIONS, WITH SPECIAL REFERENCE TO EPILEPSY

Abraham Wikler, M.D., Lexington, Ky.

Although correlations of a high degree of statistical significance have been demonstrated between changes in the electroencephalogram and certain clinical conditions, notably in epilepsy and focal organic brain lesions, every electroencephalographer is aware that dissociation of the electroencephalographic pattern and the clinical status is not uncommon. To the investigator, these facts are of great importance, since they suggest clues regarding the functional significance of rhythmical cortical electrical activity. From the clinician's standpoint, however, such discrepancies are disappointing; for, in spite of logical reasons to the contrary,[1] the hope is still widespread that a laboratory test will someday be found that will furnish clinical diagnoses. Experience with electroencephalography has shown that this is not the case, but the view is still prevalent that with the aid of the electroencephalogram one can distinguish between "functional" (usually meaning psychogenic) and "organic" (usually meaning nonpsychogenic) states.

It is the purpose of this paper to call attention to evidence that clinical and electroencephalographic changes may be widely dissociated and to discuss the significance of these findings with regard to the possible functions of spontaneous cortical electrical activity and the use of electroencephalography in clinical practice. Much of the clinical evidence is well known to electroencephalographers. However, additional illustrative material will be drawn from incidental observations on clinical-electroencephalographic studies that have been made in the course of investigations of other problems.[2] The term electroencephalogram, as used in this paper, refers to the spontaneous electrical activity of the brain as recorded clinically from scalp and, in some cases, basal leads in man, and from implanted dural leads in animals, under standard conditions.

PSYCHOSES

It is well known that the electroencephalograms of most patients with schizophrenia are within normal limits. Whether this syndrome is always associated with "cortical dysfunction" may be debatable, but there can be little doubt that impairment of cortical function is associated with both mental deficiency and Korsakoff's psychosis. Yet, in the former, entirely normal electroencephalograms are often encountered, and such dissociations have also been observed in the latter condition.[3]

Normal electroencephalograms may also be recorded in patients with cortical atrophy demonstrated pneumoencephalographically.[4] Toxic deliriums of various sorts are usually associated with abnormalities in the electroencephalogram. However, Romano and Engel [4] found that such changes are correlated with disturbance of consciousness and not with "character and expression of anxiety, the content of thought, and the nature of sense deceptions," even though the changes may be presumed to be associated with cortical dysfunction. Furthermore, in deliriums of long standing, the electroencephalogram tends to return to a more normal pattern.[5]

Occasionally during chronic barbiturate intoxication, and very frequently during the barbiturate abstinence syndrome that follows abrupt withdrawal of the drug, psychoses may be observed. It is of interest that these "toxic" psychoses may assume the form of almost any psychiatric nosologic entity in different persons and in the same person at different times. Anxiety and panic states and hallucinatory-delusional, confusional, delirious, or amnesic-confabulatory syndromes have been observed. The concomitant electroencephalographic patterns are variable, and in some instances they may be within statistically normal limits, even when the patient is extremely disturbed. When the patient has apparently recovered completely by clinical standards, the electroencephalogram may be within normal limits and yet gross evidence of "organic" brain dysfunction may be revealed by the Rorschach technique. While impairment of consciousness is usually associated with electroencephalographic changes in the barbiturate addiction cycle, the relationship is not quantitative. This may be demonstrated most strikingly in nonpsychotic subjects during chronic barbiturate intoxication.[2] The relationship between states of consciousness and electroencephalographic changes will be further discussed below.

AFFECTIVE STATES

Many of the psychotic states referred to above are associated with disturbances of affect, and, as has already been noted, they do not appear to be related quantitatively to changes in the electroencephalogram. Such dissociation can also be demonstrated by the administration of certain drugs to nonpsychotic persons. In patients with previous histories of drug addiction ("post-addicts"), the intravenous injection of as much as 30 mg. of morphine almost invariably produces pronounced euphoria, accompanied by a transient "thrill" a second or two immediately after injection, which the subjects compare with orgasm. Concomitantly, in the majority of subjects, no significant changes can be detected by inspection in electroencephalographic tracings from multiple scalp and basal leads.[2] In the same subjects, dysphoria may be induced by large doses of mescaline or N-allylnormorphine.[6] When the affective experience is pronounced, there may be a reduction in the percentage time that alpha activity is present in the record ("alpha percentage") and also in the average voltage of alpha activity. The strong affective state may not be unpleasant. Some post-addicts whose electroencephalograms showed such changes described their experience as one of "drive"; others, as one of "anxiety." Apparently the electroencephalographic changes are related not to the quality of the affective experience but to the degree of "arousal" with which it is associated.

CHANGES IN CONSCIOUSNESS

While sleep and stupor are always associated with fairly characteristic electroencephalographic changes, the latter may be encountered occasionally in persons who are wide awake, as judged by their responsiveness to whispered instruction or by their continual execution of regular voluntary activity during recording (for example, rhythmical finger tapping).[2] Dissociated electroencephalograms of this sort have been recorded with epileptic patients during seizure-free intervals and include patterns characterized by alternating rhythmical "spindles" and slow waves, or continuous 2 to 4 cps delta activity. Continuous delta activity may also dominate in the records of patients who have been treated by repeated electroshock convulsions but who were certainly not stuporous at the time the electroencephalogram was made, several days after the last treatment. During chronic addiction to methadone, patients may have electroencephalograms that consist largely of continuous 5 cps rhythmic activity, even though a pronounced tolerance has clinically developed in the subjects and they are awake throughout the period of recording.[7] Likewise, during chronic barbiturate intoxication, there is no quantitative relationship between the severity of the electroencephalographic changes and the degree of impaired consciousness. Indeed, the electroenchephalograms of the subjects who are quite wide awake may be indistinguishable from those of nontolerant subjects who have been anesthetized by intravenous injection of barbiturates.[2]

Striking dissociations of electroencephalographic "sleep patterns" and states of consciousness have also been demonstrated in animals. In the rat, moderate doses of morphine (20 mg. per kilogram of body weight subcutaneously) produced alternating fast "bursts" and slow rhythms that resembled closely those produced by pentobarbital (30 mg. per kilogram intraperitoneally). Yet, after the doses of morphine, the rat was certainly not asleep, since it had to be restrained in a holder to permit recording, while after the injection of the doses of barbiturates, the animal was anesthetized.[8]

Similar findings have been observed in the dog. In this species, a subcutaneous injection of 5 mg. per kilogram of morphine produces regular, long-recurring "bursts" and slow wave patterns, chiefly bifrontal, which disappear abruptly when the dog is called or whistled to. In contrast, similar electroencephalographic changes that are produced by intravenous injection of 13 mg. per kilogram of pentobarbital are not altered at all by these or other more intense stimuli. After the subcutaneous injection of convulsive doses (40 to 60 mg. per kilogram) of methadone in dogs, three successive types of change may be noted in the electroencephalogram: (*a*) a "burst and slow wave" pattern, (*b*) a continuous low to moderate voltage fast activity superimposed on low voltage slower rhythms, with occasional high voltage random spikes, and, finally, (*c*) recurring, rhythmic, high voltage spike discharges. Early during stage (*b*) the dog may respond readily to stimuli, but, later, the animal may be entirely unresponsive. Very striking dissociations of electroencephalographic "sleep patterns" and behavior may also be demonstrated in dogs after the administration of N-allylnormorphine (2.5 mg. per kilogram) or of atropine (5 mg. per kilogram). Although the electroencephalogram is dominated by the "burst and slow wave" pattern, the dog may be restless and a restraint may be required to permit recording.

[8] Cahen, R. L., and Wikler, A.: Effects of Morphine on Cortical Electrical Activity of the Rat, Yale J. Biol. & Med. 16: 239-243 (Jan.) 1944.

Converse dissociations have also been demonstrated. Magoun [9] reported that "In . . . animals with large hypothalamic and midbrain tegmental lesions, the excellence of electroencephalographic activation induced by afferent stimulation contrasted sharply with the poverty of associated behavorial arousal and the lesions appeared, in fact, to have dissociated the two features of the waking state."

SENSORIMOTOR ALTERATIONS

It is well known that sensory stimuli may be followed by an abrupt cessation of the alpha rhythm. In man, light stimuli are most effective. However, there is evidence that such stimuli produce their effects on the electroencephalogram not because of the specific anatomic arrangement of the visual system but because of the attention that they arouse.[10] Vivid visual hallucinations may be induced regularly in man by oral administration of about 5 mg. per kilogram of mescaline. Concomitantly, the alpha percentage may or may not be reduced. Usually, the subject's reports of visual hallucinations coincide with a transient reduction in alpha activity, but the sensory experiences may also occur in the absence of concomitant changes in the electroencephalogram. Conversely, marked changes in electroencephalographic tracings from the occipital regions may be noted in persons whose sensory visual system is unimpaired. Thus, in children with intact vision, subtentorial tumors may be responsible for "focal" delta activity in one or both occipital lobes, presumably because of upward pressure on the easily displaced tentorium.[2]

Jasper and Andrews [11] found that a close relationship could be demonstrated between the frequencies of the alpha rhythm recorded from the motor areas and the frequencies of finger tremors and that light stimuli produced parallel changes in both. However, these observers also noted exceptions in which electroencephalographic and finger tremor frequencies could be dissociated. One may observe clinically, in patients with various cerebral neurological disorders, the occurrence of maximal electroencephalographic changes in tracings recorded from locations on the scalp that are relatively remote from the presumed site of the organic lesion. Often, in these cases, no dysfunction can be demonstrated that can be related to the cortical area corresponding to the location of maximal electroencephalographic changes.[2] Further examples of the dissociation of electroencephalographic patterns and motor activity will be discussed in relation to epilepsy.

EPILEPSY

"Paroxysmal activity," or suddenly appearing high voltage fast or slow rhythms, is indeed highly correlated with epilepsy. The nature of the seizures exhibited by the epileptic patient is more closely related, however, to the locus of origin of the paroxysmal electroencephalographic discharge than to the patterns of the discharge.[12] Furthermore, there is a considerable body of evidence indicating that the "epilepsy," in the clinical sense, is determined not only by the presence of paroxysmal activity in the electroencephalogram but by the coexistence of other factors as yet unknown.

In patients with organic brain damage, as in severe post-traumatic states, or with brain tumors, focal paroxysmal abnormalities may exist in the absence of fits of any kind. In the nonepileptic post-addicts, hydration caused by vasopressin injection (pitressin®) may produce paroxysmal alterations in the electroencephalogram without seizures of any sort.[13] During the barbiturate abstinence syndrome, a severe paroxysmal mixed spike and slow wave activity may be observed in the electroencephalogram, with or without concomitant clinical seizures. Likewise, in some patients with epilepsy, severe paroxysmal disturbances may continue unabated, while overt seizures may be prevented entirely by administration of diphenylhydantoin (dilantin®) sodium. In patients with petit mal epilepsy, Jasper and Andrews [11] found that by overbreathing, " . . . one to ten of the spike and slow wave patterns would appear before clonic movements could be detected." Similar dissociations can be demonstrated in dogs after administration of convulsive doses of pentylenetetrazole (metrazol®). White and Giarman [14] have shown that in dogs anesthetized with cyclopropane, the intravenous injection of procaine may evoke long-sustained, continuous, diffuse high voltage "spike and dome" rhythms in the electroencephalogram, without any concomitant motor changes.

Dissociation of electroencephalographic patterns and clinical manifestations has also been observed in recent studies on the relation of the anterior portion of the temporal lobe to psychomotor epilepsy. While Gibbs, Gibbs, and Fuster [15] found that clinical evidence of psychomotor seizures was present in the great majority of epileptics in whom spike foci could be demonstrated in the anterior temporal lobes, this was true in only 46% of similar patients who were studied by Jasper, Pertuisset, and Flanigin.[16] In the latter series, a marked improvement after resection of the anterior temporal lobe was usually associated with the disappearances of the electroencephalographic foci, but exceptions were also noted. Conversely, subjective disturbances in patients with temporal lobe disease may be aggravated, while generalized seizures are controlled by anticonvulsant therapy.[17]

COMMENT

That clinical-electroencephalographic dissociations may be demonstrated should not be surprising, for "correlations" between two sets of data imply only the possible existence of common mechanisms. "Clinical" entities are defined arbitrarily from a utilitarian standpoint, and classifications of disorders may be revised if, by so doing, prediction or treatment is furthered. "Laboratory" data are expressed in the framework of hypothetical constructs that are implicit in the use of particular techniques; and, therefore, the functions they measure may contribute to, but rarely, if ever, determine, the clinical phenomenon under investigation. Therefore, the cause, and even the definition, of clinical entities is nearly always "multifactorial." In the case of epilepsy, the demonstration of "paroxysmal activity" in the electroencephalogram does not alone define the clinical condition. Other factors, perhaps pathologically lowered thresholds of neurons that may be depolarized by electrical field changes induced by "paroxysmal" voltage disturbances arising from independent sources, may be required for the production of epilepsy in the clinical sense. It follows, therefore, that clinical terminology should not be used to describe laboratory data. Cogent reasons have been adduced for avoidance of the terms petit mal, grand mal, and psychomotor in describing electroencephalographic patterns.[18] One may go further and suggest that the word epileptic be avoided also in describing high voltage paroxysmal discharges.

Several alternative hypotheses may be advanced to explain the clinical-electroencephalographic dissociations that have been described. However, for clinical orientation and for use in further research, it may reasonably be inferred that the alpha and beta rhythms, and the diffuse changes that may occur in the electroencephalogram in the direction of synchronization or desynchronization, are determined by activity in a specific neuronal system that is, at least in part, independent of those subserving such cerebral functions as ideation, mood, consciousness, and possibly sensory and motor activity. Such a view is compatible with known facts concerning the neurophysiological basis of the electroencephalogram and the effects of drugs thereon.[19]

The functions of such a hypothesized specific neuronal system have yet to be elucidated. That it may subserve a "scanning" mechanism concerned with sensory perception and attention has been suggested by McCulloch[20] and Walter.[21] Evidence that it may subserve homeostatic functions has been adduced by Jasper[10] and Magoun.[22] However, alternative interpretations are possible concerning the specific conditions under which such homeostatic responses are likely to occur.[23]

Such hypotheses have opened new fields for investigation that may clarify greatly the proper use of the electroencephalogram in clinical practice. At present it appears timely to stress the importance of avoiding clinical terminology in describing electroencephalographic changes and to emphasize the "multifactorial" nature of clinical entities.

SUMMARY

Clinical, physiological, and pharmacologic evidence is presented indicating that wide dissociations may occur between electroencephalographic patterns and changes in sensorium, the state of consciousness, sensation, motor activity, and ideation. It is postulated that the alpha and beta rhythms, and the diffuse changes that may occu in the electroencephalogram in the direction of synchronization or desynchronization, are determined by specific neuronal system that is, at least in part, independent of neuronal systems that subserve behavio Hence, changes in the electroencephalogram, particularly those that are diffuse and bilaterally synchronou can represent only one factor that contributes to th genesis of any clinical entity, including epilepsy.

Brucellosis of the Urinary Tract.—Brucellosis of the urinary tract should be suspected in all patients complaining of urinary symptoms whose past history reveals previous systemic infection due to Brucella. Acute cystitis and roentgenographic evidences of pyelonephritis with deposits of calcium are suggestive signs. The presence of pyuria in the absence of bacteria when routine staining and cultural methods are employed lends further suggestive evidence. Positive blood agglutination reactions for Brucella at high titers, for example, 1:400, provide corroborative evidence. It must be remembered that brucellergin skin testing and a "therapeutic trial" of Brucella vaccine therapy may greatly increase the agglutinins; the agglutination reaction has uncertain diagnostic value if performed after either of these procedures. A definitive diagnosis is established by isolation of the Brucella organisms on suitable media.

Therapy with a combination of dihydrostreptomycin and sulfadiazine in our cases produced prompt and gratifying relief of the patients' symptoms. . . . A newer and more successful method of treating brucellosis has recently been advanced. This consists of the daily administration of 750 mg. of aureomycin every six hours together with 1 gm. of dihydrostreptomycin every 12 hours. Such therapy is continued for 12 to 14 days in cases of acute brucellosis and for 21 to 28 days in cases of chronic or complicated disease. This combination of drugs appears to be superior to the combination which we employed. —Laurence F. Greene, M.D.; Lyle A. Weed, M.D., and Donald D. Albers, M.D., Brucellosis of the Urinary Tract, *The Journal of Urology*, May, 1952.

TREATMENT OF MALARIA WITH A SINGLE DOSE OF AMODIAQUINE OR CHLOROQUINE

Mark T. Hoekenga, M.D., La Lima, Honduras

Since the development of 4-aminoquinoline compounds, particularly chloroquine (aralen® [Winthrop-Stearns]) and amodiaquine (camoquin® [Parke-Davis]), the treatment of malaria has become much simpler than it was a few years ago. Published reports stress the rapidity with which symptoms are alleviated and the speed with which parasites disappear from the peripheral blood when either of these drugs is administered.

Chloroquine and amodiaquine have the following pharmacologic and clinical properties in common: 1. They are rapidly and essentially completely absorbed from the gastrointestinal tract of experimental animals and presumably of man. 2. They are distributed unequally in the body tissues and are present in much higher concentrations in some tissues than in blood plasma. 3. They are slowly excreted from the body on cessation of drug therapy. 4. They are highly effective in terminating acute attacks of malaria due to either Plasmodium falciparum or P. vivax. 5. They usually result in complete eradication of P. falciparum infections. 6. They decrease the number and frequency of P. vivax relapses. 7. Neither has any marked gametocidal effect. 8. Neither has any marked effect against sporozoites, and therefore both are without prophylactic value. 9. Toxic effects with therapeutic doses are insignificant.

Chloroquine is 7-chloro-4-(4-diethylamino-1-methylbutyl-amino)-quinoline. In the World War II evaluation of potential antimalarials, it emerged as one of the more active and least toxic quinoline derivatives. Consequently it was employed widely, and has given satisfactory results in thousands of infections. It is commonly supplied in the form of the diphosphate as 250 mg. tablets, of which 150 mg. (or 60%) are chloroquine base. The usually recommended treatment of acute malaria in nonimmune persons consists of administration of 4 tablets (1 gm.) as an initial dose, followed by 2 tablets (500 mg.) after 6 to 8 hours and 2 tablets on each of two successive days.

Amodiaquine is 4(3'diethylaminomethyl-4'hydroxy-anilino)-7-chloroquinoline, supplied in the form of dihydrochloride dihydrate. It was synthesized in 1946, and subsequent trials in several parts of the world have demonstrated good results with doses frequently even smaller than those recommended for chloroquine. The 300 mg. tablets contain 200 mg. of the base. Three tablets equal 0.6 gm. of the base, and 2 tablets 0.4 gm.

From the time of its first clinical trials, amodiaquine has been frequently employed as a single dose treatment and as a one day treatment. This is true also for chloroquine, but most clinicians have preferred the three day regimen referred to above. To date, there seems not to have been any large scale study that directly compares the therapeutic effects of these two compounds, gram for gram.

In our hands [1] 0.6 gm. of amodiaquine base in a single oral dose has been completely satisfactory for treatment of acute attacks of both P. falciparum and P. vivax malaria in northwestern Honduras. We wondered whether chloroquine might be as effective when given in a comparable single dose in the same geographic area. One previous publication [2] provided a clue. Butts reported a series of 449 cases of malaria in Honduras, Costa Rica, and Panama, in which treatment with chloroquine was given on 16 schedules; 92 of this group received single doses of the drug varying from 0.08 gm. of base to 0.62 gm. of base. Butts noted that these amounts of chloroquine "appeared almost as satisfactory in this adult immune group as large doses extended over a three-day period." We thought it worth while to explore further the practicability of single dose treatment with chloroquine or amodiaquine on a comparative basis.

MATERIAL AND METHODS

This study is based on the treatment of 600 persons who resided in or near the Tela Railroad Company (United Fruit Company) headquarters at La Lima in northwestern Honduras. This is an area where Anopheles albimanus is the principal vector and where malaria is endemic all year around, but of slightly decreased incidence during the dry season from May to September. Because of the endemicity of the disease, the adult native population may be considered as a relatively immune group. All of these patients were hospitalized between February, 1950, and May, 1951, in the Tela Railroad Company Hospital located in La Lima.

The ages ranged from 7 years to 61 years. Eighty-six per cent were males and 14% were females, the difference being explained by the fact that the experiment was conducted largely on the male medical wards of the hospital. All were of mestizo stock, and represented various mixtures of Indian, Negro, and Spanish ancestry.

Amodiaquine was given to 380 patients, including 325 of the previously reported group.[1] They were placed in one of four groups to which either 0.4 gm., 0.6 gm., 0.8 gm., or 1.0 gm. of the base was given in a single dose. Chloroquine was given to 220 patients. As a result of experience already gained in the amodiaquine series, only two chloroquine schedules were employed: 0.45 gm. of base (0.75 gm. of aralen®) or 0.6 gm. of base (1.0 gm. of aralen®) given in a single dose.

Whichever of the two compounds was employed, the amount of drug and the time of administration were not related to the parasite density, to the stage of the parasite cycle observed in the blood film, or to the degree of fever. As soon as a diagnosis was confirmed by blood film, the patient was treated with whichever schedule was currently in use. Amodiaquine treatment was given from February, 1950, through December, 1950. Chloroquine treatment was given from January through May, 1951. The oral temperature was recorded every four hours on all patients. Throughout the hospitalization, thick blood films were examined twice daily, at 6 a. m. and at 3 p. m. The groups were comparable in respect to degree of parasitemia when treatment was started.

RESULTS

Clinical Response.—By reference to the table, it can be seen that only the 0.45 gm. dose of chloroquine did not prove to be quite satisfactory. There is indication that

patients with P. falciparum malaria treated with 1.0 gm. of amodiaquine base achieved a normal temperature a little more quickly than persons given lesser amounts of this drug, but a similar difference is not noted in the temperature response of patients with P. vivax malaria. In all but nine patients headache, malaise, vomiting, joint pains, and other symptoms attributable to malaria disappeared within 36 to 48 hours, regardless of the treatment given. Convalescence was usually rapid; most patients were able to return to work by the fourth day after treatment.

Parasitological Response.—The results are given in detail in the table. In tabulating the number of hours before disappearance of parasitemia, the persistence of gametocytes was not included. Although precise records on gametocyte clearance were not kept, our impression does not differ from the accepted concept that the 4-aminoquinoline compounds are only weakly gametocidal. P. vivax gametocytes usually disappeared promptly, but P. falciparum gametocytes often persisted until after further treatment with primaquine (8-4 [amino-1-methylbutylamino]-6-methoxyquinoline) or pentaquine (8-[5-isopropylaminoamylamino]-6-methoxyquinoline).

* Later relapses are not indicated in this table.
† The figure in parentheses represents the number of cases in which the response to the single dose treatment was not satisfactory.

Treatment Failures.—Among the 220 persons who received chloroquine, there were 6 who did not respond to this treatment (one from the 0.6 gm. schedule, the others from the 0.45 gm. group). These six persons continued to have schizonts in the peripheral blood as well as elevation of temperature and other clinical symptoms that necessitated re-treatment. All responded satisfactorily to a three-day chloroquine regimen. Among the 380 individuals included in the amodiaquine groups, there were 3 who did not respond, all of whom had been treated by the 0.4 gm. schedule; they responded promptly to re-treatment with 1.0 gm. of amodiaquine. The distribution of these failures is included in the table.

Relapses.—The known number of relapses is small. Only 12 persons reported back to the hospital or outpatient dispensaries with return of symptoms and parasitemia. All had had malaria due to *P. vivax*. Four of these had been treated with 0.4 gm. of amodiaquine, five with 0.45 gm. of chloroquine, and three with 0.6 gm. of chloroquine. It is possible that some others may have taken antiplasmodial drugs on return of fever without coming to our attention in the hospital or at the dispensaries. The number of these is believed to be small, however, because most of these persons are too poor to privately purchase antimalarial medicines.

Toxicity.—In the dosages administered, no serious toxic effects were noted. Five of the amodiaquine-treated patients and four of the chloroquine-treated patients vomited after administration of the drug; in all of these, the tablets were well tolerated when administration was repeated, and so it is more logical to ascribe the vomiting to the disease than to the medicaments. Both compounds were administered to persons with malaria complicated by a number of other conditions, such as cardiovascular disease, marked malnutrition or cachexia, hepatic or renal disease, pulmonary diseases, and advanced pregnancy. In no instance was there clinical evidence of drug toxicity or intolerance.

COMMENT

It should be emphasized that this study was done in an area where malaria is endemic and the adult native population is presumably highly immune. Results of treatment among a nonimmune population or among an immune population of another location may be less favorable than our results, or might be better. Variation in parasite strain may also produce responses not completely in line with our observations.

In this locality it appears to be practical to treat most patients with malaria on an ambulant basis with very few tablets of either amodiaquine or chloroquine in a single oral dose. Probably this will prove to be true for many other endemic areas in the world, and in these areas such treatment will be economical of money, time, and hospital facilities. However, we do not advocate ambulant treatment for all cases; patients with P. falciparum infections, particularly, should be hospitalized for 36 to 48 hours whenever this is possible in order to better cope with potential complications.

The time for disappearance of parasites from the blood is stated conservatively in all instances. Since blood films were made only two times a day, at 6 a. m. and at 3 p. m., the disappearance of parasites would only occasionally be noted shortly after its actual occurrence; frequently a lapse of a few hours could be presumed between the actual disappearance of parasites and its demonstration at the next regular time for blood examination.

None of the patients received any medication parenterally. Amodiaquine has been used parenterally with success [3] elsewhere, and chloroquine has been employed intravenously, with success here in Honduras.[4] It is essential that reliable preparations such as these that can be given parenterally be always available for treatment of those severely ill patients who, because of coma or vomiting, are unable to take the medication orally.

SUMMARY

Six hundred Hondurans were treated for malaria with a single oral dose of either amodiaquine (camoquin®) or chloroquine (aralen®). Four amodiaquine doses were used among 380 patients: 0.4 gm., 0.6 gm., 0.8 gm., and 1.0 gm. of the base. Two chloroquine schedules were employed among 220 patients: 0.45 gm. and 0.6 gm. of the base. All of the amodiaquine groups as well as the 0.6 gm. chloroquine group showed satisfactory clinical and parasitological responses. The response in the 0.45 gm. chloroquine group did not prove entirely satisfactory.

Only 9 individual treatment failures were observed among the 600 patients. Six patients had received small amounts of chloroquine (0.45 or 0.6 gm. of base), and three had received 0.4 gm. of amodiaquine. These cases do not include those in which there was persistence of gametocytes in the peripheral blood, which occurred in a small but unknown number of additional persons. Twelve relapses of P. vivax malaria were observed. Four of these occurred after treatment with 0.4 gm. of amodiaquine and the others occurred after small doses of chloroquine (0.45 gm. or 0.6 gm.). The toxic side-effects of both compounds are insignificant with the dosages used. Obviously, it is of great advantage to have two antiplasmodial agents that are applicable to mass treatment with a single small oral dose.

A STUDY OF RUBBER ADHESIVES IN SHOES AS THE CAUSE OF DERMATITIS OF THE FEET

Irvin H. Blank, Ph.D.
and
Owen G. Miller, M.D., Boston

Dermatoses of the feet are troublesome and rather common. They range from mild fissuring between the toes to severe vesiculation, oozing, and edema of almost the entire foot. They may be of short or long duration. They may be sufficiently severe so that a physician is consulted early in the course of the disease, or they may be mild enough to have been self-medicated for many months before the aid of a physician is sought. The signs and symptoms of different dermatoses of the feet may be sufficiently similar so that it becomes difficult to diagnose and treat the dermatoses. It is the purpose of this paper to discuss the specific agent that causes allergic eczematous contact-type dermatitis of the feet, a condition that we believe is now being confused with epidermophytosis, bacterial infections, and inflammatory skin conditions from other causes. This condition clears readily when the allergen is eliminated. Usually we have been able to determine the specific allergen in these cases, and we can now state which allergens should be used for testing patients with such conditions.

In 1949, Gaul and Underwood [1] pointed out that many dermatoses of the feet, which are diagnosed and treated as fungous infections, are more correctly diagnosed as a dermatosis caused by an irritant or allergen in the shoes of the patient. They were able to support their opinion with positive results of patch tests to various portions of the patients' shoes. The patch test data led Gaul and Underwood to be suspicious of the adhesive materials in the shoes. They attempted to obtain more information about these materials but reported, "Letters to companies manufacturing adhesive materials brought two samples and a decided reluctance to divulge their ingredients."

Jordon [2] studied 43 cases of dermatitis of the feet and concluded that resinous shoe linings were the cause of the dermatitis, though he was unsuccessful in obtaining any positive reactions to any resin or other single ingredient in the resinous lining in any case that he studied. A study of rubber footwear as a cause of foot eczema led Bonnevie and Marcussen [3] to the opinion that the specific allergen was one or more of the accelerators of the mercaptobenzothiazole type, which were used in the manufacture of the rubber.

During the past year we have studied 24 cases of dermatitis of the feet that seemed to be caused by shoes. In each of the cases there was a history of a dermatitis that could be correlated to the wearing of one or more pairs of shoes. Positive patch test reactions to portions of the shoes were obtained to support the history in 20 of the cases. In three we were unable to test the suspected shoes. In only one were we unable to obtain a positive reaction from any of the shoe materials.

Twenty-one of the 24 patients were women, and in a large majority of them we found positive patch test reactions to the light-colored, combined, cloth linings in the

shoes. These combined cloth linings usually consisted of a faille and a coarser backing cloth, which were held together with a rubber adhesive. The close association of dermatitis due to shoes with dermatitis due to rubber has been discussed in each of the previously cited references. We felt that the rubber adhesive used in the combined linings might be the cause of the dermatitis, and we proceeded on this basis.

Some survey testing of the patients indicated that it was likely that they were sensitive to an antioxidant or accelerator used in the rubber adhesive, as in Bonnevie and Marcussen's [3] cases. Ten representative antioxidants and 17 accelerators [4] used by the rubber industry were made available to us, and as many of the patients as possible were tested with these materials. Numerous vesicular reactions were observed, but it became apparent that a good many of the patients reacted to none of the materials tested. Also, it was not known definitely that these particular antioxidants or accelerators were used in the fabrication of the adhesives used in the combined linings.

Subsequently a manufacturer of combined linings supplied us with the separate ingredients and combinations of ingredients that are present in the adhesives used in some combined linings. These ingredients included various kinds of rubber, an antioxidant, a tackifier, a plasticizer, a peptizing agent, and two accelerators. It soon became apparent that the patients reacted violently to the antioxidant and to any combination of ingredients containing the antioxidant. This antioxidant had not been among those previously used by us for patch tests. Some of the patients who had reacted to none of the other antioxidants or accelerators were recalled and were shown to react positively to this antioxidant. Unfortunately all patients could not be recalled for testing with the new material. This antioxidant is the monobenzyl ether of hydroquinone.

Table 1 shows the patch test data for 21 of these patients. (The three patients who showed no reactions to any of these chemicals are omitted.) Five of the 17 accelerators contain a compound possessing a mercaptobenzothiazole radical:

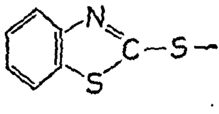
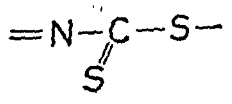
† These patients were tested with special shoe linings (see text).



Four contain a compound that has a dithiocarbamyl radical:



$$=N-\underset{\underset{S}{\|}}{C}-S-$$

Two are mixtures of both types of compounds. The other accelerators and antioxidants have various chemical

---

4. Mr. C. C. Davis of the Boston Woven Hose and Rubber Company supplied these materials.

structures. All the materials were tested in 1% concentration in petrolatum. The tests were made on the upper arm, were kept on the skin for 48 hours, and were read one hour after removal. Only vesicular reactions are recorded as positive; no reaction and mildly erythematous reactions are recorded as negative; and "0" indicates that the patient was not tested. These data are summarized in table 2.

The numbers in parenthesis in table 2 show the number of individual accelerators of the type indicated to which the patient showed reactions. The patients have been divided into five groups. In group I are the patients who reacted only to monobenzyl ether of hydroquinone or those whom we suspect would have reacted to this material had we been able to recall them for testing. (These latter patients had positive reactions to typical combined linings and were not sensitive to any other antioxidant or accelerator.) In group II are the patients who were not sensitive to monobenzyl ether of hydroquinone but were sensitive to the mercaptobenzothiazole or dithiocarbamyl compounds. In group III are the patients who were sensitive to monobenzyl ether of hydroquinone and to either the mercaptobenzothiazole compounds or the dithiocarbamyl compounds. In group IV are patients who were sensitive to mercaptobenzothiazole compounds and occasionally to some other compound but who were not tested to monobenzyl ether of hydroquinone. In the last group are three patients who showed no positive reactions to any of the antioxidants or accelerators. One was sensitive to a typical combined lining, one to a box toe in the shoe, and one to brown dyed leather.

† These patients were tested with special shoe linings (see text).

It is our opinion that monobenzyl ether of hydroquinone is frequently the allergen in dermatoses that arise from the combined linings of shoes. The patients who were sensitive to this antioxidant often gave a history of dermatitis from other rubber articles (garters, elastic, rubber tubing used for a tourniquet, and adhesive plaster). Patients who reacted to the antioxidant, monobenzyl ether of hydroquinone, obtained from a rubber company, also reacted to the pure chemical, monobenzyl ether of hydroquinone, as obtained from the Eastman Kodak Company. This would tend to rule out the possibility that the patients might be reacting to an impurity in the antioxidant. They often showed a severe vesicular reaction to a concentration of 1 part of the chemical in 10,000 parts of petrolatum. Those whom we have tested do not react to hydroquinone.

The combined lining manufacturer made two linings for us, which were the same in all respects except that one contained monobenzyl ether of hydroquinone and an accelerator of the mercaptobenzothiazole group and the other contained neither of these materials. All other ingredients were identical in the two linings.

These linings were fabricated into shoes,[5] one lining in the right shoe and the other lining in the left. Pairs of these shoes were given to four patients (cases marked with a dagger [†] in groups I and III). The patients were not told that the linings were different, nor could they tell any difference from looking at the linings. They were asked to wear the shoes for short periods of time and report to us. Each patient showed vesicles on the dorsum of the foot on which was worn the shoe made from the lining containing monobenzyl ether of hydroquinone and the mercaptobenzothiazole accelerator. This vesiculation occurred 12 to 24 hours after the shoes had been worn for approximately 30 minutes. The other foot remained normal.

It would not be possible from this experiment to determine whether the monobenzyl ether of hydroquinone or the accelerator was the allergen for two patients (cases 14 and 15), since they were sensitive to both substances. For two others (cases 1 and 2), however, monobenzyl ether of hydroquinone must be the allergen, since these two patients were not sensitive to the accelerator.

COMMENT

Monobenzyl ether of hydroquinone is the antioxidant that was reported by Oliver, Schwartz, and Warren [6] to have caused leukoderma among tannery workers who wore rubber gloves that contained this antioxidant. There have been other reports [7] of the depigmentation that this compound causes. The ability of this compound to cause allergic hypersensitivities has not been stressed. Schwartz [8] stated that, on trying to cause depigmentation of his own skin, he caused an eczematous-type reaction. In the discussion of the Oliver, Schwartz, and Warren paper,[8] Sulzberger stated that, in an attempt to cause depigmentation with monobenzyl ether of hydroquinone by experimental patch tests, he produced an eczematous, allergic specific sensitization in "approximately 50 per cent of the cases" by the application of full-strength monobenzyl ether of hydroquinone. Lockhart and Loewenthal [9] commented, "Although the reaction of contact-type, eczematous dermatitis is obtained by patch testing, several authors believe that depigmentation may occur without such initial reaction." Botvinick[10] reported a case of leukoderma and dermatitis from a pair of rubber gloves that were shown to contain monobenzyl ether of hydroquinone. We seldom saw evidence of depigmentation in any of our patients. It is true, however, that we did not follow many of these patients for very long after the acute phase of the dermatitis had subsided.

Monobenzyl ether of hydroquinone has been studied mostly with respect to its depigmenting action among rubber workers and wearers of rubber articles. Its eczematizing action has been observed during attempts to cause depigmentation experimentally. Allergic, eczematous, contact-type dermatitis among wearers of rubber articles containing monobenzyl ether of hydroquinone has been less frequently reported. The manufacturer of this material has reported to us that no dermatitis has occurred among the workmen who handle this antioxidant. Nevertheless, we suspect that its sensitizing index is relatively high when it gets into contact with the skin in shoes or adhesive plaster, though certainly not nearly as high as the 50% reported by Sulzberger in his small patch test series. It seems sufficiently high so that every effort should be made to prevent the use of monobenzyl ether of hydroquinone in rubber articles that come into contact with the skin.

Allergic, eczematous contact-type dermatitis to other antioxidants and accelerators that we tested is less frequent. It must not be concluded that those compounds that showed completely negative reactions in this group of patients are safe compounds to use. It may be that these patients had not previously been in contact with these compounds and that, therefore, they would not be expected to show a reaction to them. A good example of this situation is the compound hexamethylenetetramine, an accelerator that is seldom used by the rubber industry today. It has been discarded because it was found to have a high index of sensitization. Also, it must be remembered that substances that are not allergenic for this group of patients might sensitize even a higher percentage of persons from the population at large.

In a suspected case of dermatitis caused by shoes it is certainly not necessary to test to the large group of materials we used. Three types of compounds could be used: (1) monobenzyl ether of hydroquinone, (2) 2-mercaptobenzothiazole, and (3) tetramethylthiuram monosulfide. If these three compounds are used, it is probable that reactions will be found to one or more of them if the shoe dermatitis is caused by one of the rubber ingredients of the shoes.

We wish to emphasize the opinion previously expressed by Gaul and Underwood [1] that, when a patient is seen with a dermatitis of the feet, it is important to remember that the dermatitis may result from an allergic hypersensitivity to some ingredient in the shoe. In the cases of this type that we have studied, the most frequently observed allergen was an antioxidant or accelerator used in the rubber adhesives in the shoes.

SUMMARY

An acute dermatitis of the feet may be an allergic, eczematous, contact-type dermatitis. The allergen for those patients we have studied was most frequently the antioxidant monobenzyl ether of hydroquinone, which is used in the rubber adhesive in the combined linings of the shoe. Some of these patients were specifically sensitive to other rubber antioxidants and accelerators.

STERILITY OF MARKET COTTON

John H. Silliker, Ph.D.
and
Eugene P. Hess, M.S., Los Angeles

The consumer's guarantee of sterility in products labeled "sterile" lies chiefly with the producer. In the case of "sterile" market cotton,[1] the control program of the Food and Drug Administration, in the Los Angeles area at least, consists of taking random samples at periodic intervals. These are sent to the Federal Drug Administration in Washington, D. C., for sterility testing. Results of these investigations are not available. In view of this, it was decided to make a survey of "sterile" market cotton to determine whether the present control program is adequate to insure sterility in all packages of cotton.

EXPERIMENTAL DATA

Procurement.—Samples of "sterile" market cotton were purchased from retail stores in various parts of the city of Los Angeles. Generally a single 4-oz. roll of a nationally prominent brand was purchased from each retailer. At the time of purchase, no mention was made of the survey being conducted. Only undamaged packages, labeled "sterile," were used.

Sampling.—For the purpose of sampling, a large transfer chamber containing a Westinghouse sterile lamp

[1] Purified cotton (sterile absorbent) U. S. Pharmacopeia XIV.

was used. The chamber was completely enclosed except for hand inserts. Previous to use, the chamber was completely swabbed with a technical grade of benzalkonium chloride (roccal,® 1: 1,000 solution). All sampling procedures were carried out under ultraviolet rays.

The outside of each package of cotton was thoroughly wetted with benzalkonium chloride before being placed in the transfer chamber. The moist package was exposed to the ultraviolet rays for at least 10 minutes before the outer covering was broken. This allowed for complete drying in a sterile environment. The cotton roll was removed from the package, and the paper enclosing the roll was swabbed with benzalkonium chloride. The first sample was taken from the end of the roll, and subsequent samples were taken at intervals of approximately 12 in., moving toward the center of the roll. In total, five samples were obtained from each 4-oz. roll.

Sterile applicator sticks were handled with hemostats, which were previously allowed to stand in benzalkonium chloride for a period of three minutes and then flamed before use. An amount of cotton, approximating that used for a throat swab, was twisted on the end of the stick. The stick was then broken at a point above the sample, with sterile hemostats used for all manipulations, and the swab was dropped into an 8-oz., wide mouth, sterile bottle containing approximately 50 ml. of sterile fluid thioglycollate medium (as recommended in the U. S. Pharmacopeia for sterility tests). Previous to use the outer surfaces of the culture bottles were swabbed with benzalkonium chloride, and the bottles were then allowed to stand in the chamber for 10 minutes.

The bottles containing the medium were incubated for 48 hours at 37 C previous to inoculation as a check on the initial sterility for the medium. Along with each roll sampled, a control bottle was inoculated with a 3-cm. section of a sterile applicator stick that was handled in exactly the same manner used for all other samples taken. It must be emphasized that the control bottle for each roll of cotton tested was inoculated in the same atmosphere as the test samples and had equal opportunity for chance contamination.

The samples thus obtained were incubated at 37 C for three weeks and examined at weekly intervals. Those bottles showing turbidity were checked for the presence of micro-organisms by means of microscopic observation of gram-stained smears. The viability of the organisms was determined by subculture on nutrient agar.

Results.—Table 1 summarizes the results obtained from the examination of 85 different rolls of market cotton. It can be seen that in 14 out of 413 different samples viable organisms were detected. Twelve out of 85 rolls of cotton contained viable micro-organisms. In two instances two positive results were obtained from the same roll. Of the 14 samples containing viable organisms, one was obtained from the outermost portion of the roll; five were obtained 1 ft. from the outside; four were obtained 2 ft. from the outside; two were obtained 3 ft. from the outside; and two were obtained from the innermost center of the roll. As nearly as could be determined the positive samples each contained a single type of bacteria. Gram-positive cocci were found in seven samples, gram-negative, non-spore-forming rods in three, a gram-positive, anaerobic, spore-forming rod in one, a gram-negative spore-forming rod in another, and the gram-positive rods in two.

ISOLATION AND DETERMINATION OF HEAT RESISTANCE OF CONTAMINANTS FOUND IN MARKET COTTON

Four of the positive samples were selected for further study. Pure cultures were obtained from the thioglycollate broth with the use of the loop dilution and streak plate techniques. The cultures thus obtained were as follows: no. 49, short, gram-negative, non-spore-forming, aerobic rods; no. 52, gram-positive micrococci (albus type); no. 58, short, gram-positive rods showing extreme pleomorphism with a definite tendency to show coccoid forms; and no. 63, gram-negative, aerobic, spore-forming rods.

For the determination of the heat resistance of the above isolates, the organisms were grown at 28 C in bottle slants containing nutrient agar and harvested at the point of maximum growth. The cells were suspended in M/20 phosphate buffer with a pH of 7.0, washed twice by centrifugation, and resuspended in the buffer. Plate counts were made from the final buffer suspension.

TABLE 1.—*Results of Sterility Tests on Market Cotton* *

Brand	No. of Rolls Examined	No. of Samples	No. of Controls	No. of Positive Samples Showing Viable Organisms	No. of Positive Controls Showing Viable Organisms
A................	15	75	15	2	0
B................	15	75	15	5	0
C................	15	75	15	2	0
